Various fixed-wing aircraft are available for medical transport. These range from unpressurized light planes with single- or twin-piston engines to pressurized turboprops and jets. The selection of the ideal aircraft depends on the nature of the air medical mission.

Air Medical Flight Crew

Air medical crew members represent the broad spectrum of health care providers. AMT services that provide critical care transport, advanced life support, or specialty care transport must staff the vehicle with a minimum of two medical personnel to provide direct patient care.[10,11] The majority of AMT programs in the United States provide critical care transport teams composed of one registered nurse and an additional crew member (paramedic, respiratory therapist, physician, or a second nurse); most common is the nurse-paramedic crew.[12] AMT crew configuration may also be mission dependent. A service may at times believe that it is appropriate to use a single medical crew member. For example, it may be appropriate while transporting a stable patient on a routine interfacility transport. Certain flight conditions and situations may also necessitate flying with a single crew member, including heat, humidity, altitude, distance, fuel on board, and weight of the patient.[12]

Flight nurses generally have extensive experience in intensive care units or emergency departments. They may be specialized within the transport team to care for adult, pediatric, or neonatal patients. Paramedics often make their greatest contribution in the transport of critical patients from the scene of illness or injury. Respiratory therapists bring expertise in airway and ventilator management and oxygen delivery systems. Flight physicians may be residents or attending physicians. Much of the early research in AMT crew composition focused on the need for the flight physician. Although this remains controversial, what seems clear is that the crew used by an AMT program must be explicitly tailored to the needs of the community and the patients it serves.

The AMT environment imposes unique considerations on the air medical flight crew that can influence their ability to provide patient care. Human factors work has shown that most medical care procedures are more difficult to perform in an AMT vehicle than in other ground-based settings.[13] Auscultation of the heart and lungs, palpation of pulses, performance of cardiopulmonary resuscitation, endotracheal intubation, radio communications while using a respirator or face mask, and recognition of visual alarms may all be impaired while aloft.[14-19] In addition, fatigue, motion sickness, exposure to engine exhausts, an erratic pattern of work activity, and the high risk involved in AMT operations may affect task performance significantly.[20-22] Seizures from photic stimuli associated with rotor motion ("flicker illness") has also been reported.[23] High-fidelity simulation of air medical missions can acquaint flight crew to the novel environment, but fiscal and personnel costs may be prohibitive.[24]

Medical Direction

All air medical services require the active involvement of a physician as medical director responsible for supervising, evaluating, and ensuring the quality of medical care provided by the AMT team.[25] Emergency physicians play a significant role, with nearly 50% of all air medical directors having a background in emergency medicine.[26] The medical director must have the final authority over all clinical aspects of the air medical service and should ensure that the flight crew have adequate training and qualifications to optimize patient care. Medical care policies and procedures should be established, including specific provisions for on-line and off-line medical control. The Air Medical Physician Association and the National Association of EMS Physicians have established guidelines for the medical director of an air medical service.[27,28]

Safety

Safety is the predominant concern of air medical operations, and ensuring safe flight is a fundamental part of every flight program.[29] Safety must also be an overriding consideration in weighing the risks and benefits of AMT. The role of aircraft pilots and mechanics is essential to the airworthiness of the vehicle, and medical personnel must also be proficient in both routine and emergency operations in and around the aircraft. Checklists may aid in safety practices but alone may not detect significant operational concerns.[30] Crew fatigue and other self-imposed stresses that could affect safety, such as the use of prescription or over-the-counter medications, tobacco, and alcohol, must be scrupulously avoided.

Weather requirements ("minimums") must be strictly enforced. On receipt of a flight request, the pilot must verify the weather conditions and the condition of the aircraft. To ensure impartiality, the pilot should not be told of the patient's condition or acuity. The pilot maintains the unquestioned right to decline a mission because of aircraft or weather considerations.

The practice of "helicopter shopping" has been a major factor in a number of fatal HEMS events. Helicopter shopping refers to

www.ketabpezeshki.com 66485457-66963820

Figure 191-2. Landing zone safety is paramount to delivery of patients to hospitals. (Photograph courtesy Dan Lemkin, MD.)

the practice of a requesting EMS agency or hospital calling numerous HEMS operators until one agrees to accept a flight without disclosure to the accepting HEMS operator that other programs have declined the flight because of bad weather or other safety concerns.[31,32] The practice has been so common that in 2006, the Federal Aviation Administration issued a letter to all state EMS directors describing helicopter shopping and requesting that they take action to prohibit this practice.[33]

Landing Zones

Helicopter landing zones are inherently dangerous places. The most obvious risk of injury is impact with rotor blades. This danger is heightened during ground operations because the blades dip lowest to the ground at the slower rotor speeds associated with engine start-up and shutdown. Injuries also may occur as a result of debris being propelled through the air by "rotor wash," increased noise levels and an inability to hear warnings, and slippery surfaces found on exposed landing sites.

Many hospitals have designated landing areas that are appropriately lit and secured (Fig. 191-2), with fixed coordinates and predesignated liftoff and approach patterns. However, most primary (scene) responses occur at unmarked sites. Ground personnel must be trained to designate and secure a safe landing zone for helicopter operations. AMT programs have an obligation to help train ground staff on proper landing zone setup and conduct (Boxes 191-1 and 191-2).

Helicopter flights direct to the scene of an accident pose unique risks to AMT from hazards near the landing zone. This risk is heightened at night. In response to this concern, out-of-hospital care providers and flight programs have found it beneficial and safer to use a hospital helipad for rendezvous. This practice raised concerns about Emergency Medical Treatment and Active Labor Act (EMTALA) responsibilities to provide a medical screening examination for these patients. In May 2004, the Centers for Medicare and Medicaid Services resolved this issue, noting that the use of a helipad on hospital property does not trigger EMTALA provisions as long as the helipad is being used only as a stopping place for EMS personnel to rendezvous with AMT, facilitating transport of a patient to the closest appropriate facility.[34]

Other adjuncts to landing zone safety and night operations in general are night vision goggles and terrain avoidance warning systems. A growing number of AMT programs are equipping their aircraft with these sophisticated technologies in an effort to enhance safety.

Box 191-1 Landing Zone Safety

Vehicles and personnel should be kept at least 100 ft from the landing zone.
Spectators should be kept at least 200 ft from the landing zone.
No smoking or running is permitted within 50 ft of the helicopter.
All items (e.g., intravenous lines, poles) should be kept below shoulder height.
The flight crew opens and closes aircraft doors.
The flight crew directs and supervises the loading and unloading of the patient and equipment.
Ground personnel should use eye and ear protection.
Approach the helicopter *only* when signaled to do so by the pilot or an onboard crew member.
Approach and depart the helicopter *only* forward of the rear cabin door and in a crouched position with your head down.
Never approach or depart from the rear of the helicopter.
Stay clear of the tail rotor; it is virtually invisible and extremely dangerous.
If the aircraft is parked on a slope, approach and depart on the downhill side (greatest clearance under the blades).
Keep the landing zone clear of (or hold on to) all loose articles (e.g., hats, scarves, sheets, pillows).
Protect patient from the dust and debris.
Follow the flight crew's instructions at all times.
In disaster situations and mass casualty incidents, victims, witnesses, and spectators may become hysterical or exhibit signs of an acute situational reaction. These individuals must be kept clear of the landing zone and helicopter *at all times.* Injured victims who exhibit this behavior should *not* be triaged for helicopter transport, or they should be transported *only* with adequate physical or chemical restraints in use.
If you do not know, ask.

Integration of Air Medical Transport within Emergency Medical Service Systems

AMT should be an integral resource within a comprehensive EMS system. Integration begins with the establishment of geographic service areas. Service areas may be determined on the basis of program mission description, aircraft range and speed, placement of specialty centers and receiving facilities, and population densities. As a general rule, helicopters are generally less useful in urban settings because of the proximity of health care facilities and a lack of open and safe landing zones. Paramedics, emergency medical technicians, and other public safety personnel should be provided with guidelines specifying when AMT should be considered. These protocols are best developed by EMS medical directors in close collaboration with their air medical colleagues.

CLINICAL CONCEPTS AND PATIENT CARE

Although virtually all types of patients have been transported by air medical services, available data do not allow prospective, definitive identification of which patients will benefit from flight. Many questions about the triage of patients to air or ground transport, the efficacy of air medical care, and the precise effects of AMT on morbidity and mortality in medical and surgical conditions remain unanswered. There are volumes of studies indicating what patients *can* be cared for in the air medical environment and what skills and equipment *can* be used, and there are also many studies

www.ketabpezeshki.com 66485457-66963820

Box 191-2 Landing Zone (LZ) Requirements for Air Medical Transport

Landing Area

LZ should be as close as possible to the scene or hospital entrance, but not so close that it may interfere with ground operations or patient care.
LZ should be at least 100 × 100 ft.
LZ should be as flat and level as possible.
LZ *must* be clear of debris.

Hazards and Obstructions

Identify all potential hazards that may be on the ground or near the approach/departure path of LZ.
LZ should be clear of wires, poles, trees, buildings, vehicles, and spectators.
Road cones, ropes, tape, and barricades are *not* recommended for use near LZ.
Perimeter of LZ should be at least 50 ft away from potential obstructions and hazards.
LZ should be located *upwind* from any hazardous material incident.

Approach and Departure Path

Path should point into the wind and be free of obstruction to an altitude of 500 ft above the surface.
Path should *not* pass over command posts, treatment areas, or operationally congested areas on the ground.

Day Operations

Use radio communications and hand signals.
Stand with your back to the wind.

Night Operations

Use radio communications and lighting to designate LZ.
Spotlights should be directed at the top of possible hazards, *not* toward the approaching or departing aircraft.
Position a portable light, vehicle headlights, emergency vehicle flashing lights, flare, or chemical stick at each corner, with a fifth light upwind.
Nonessential lights should be turned off.

Light Sources

Lights *must* be clear of LZ.
If portable, lights *must* be well secured.
Never point lights toward an approaching or departing helicopter.

Wind Indicator

Indicator may be a wind sock, flag, flare, or smoke.
Indicator *must* be clear of LZ.
If portable, indicator *must* be well secured.

Courtesy University of Chicago Aeromedical Network (UCAN), University of Chicago Medical Center and Illinois Association of Air and Critical Care Transport (IAACCT), 2008.

demonstrating benefit to air transport. Unfortunately, there is a relative paucity of clinical investigation addressing potential solutions to the problems of triage and appropriate use. What does seem clear is that medical flight is generally associated with safe patient care and a low incidence of adverse effects.[35] In an effort to ensure that AMT resources are used wisely, the Air Medical Physician Association (AMPA) has established a detailed medical condition list for the appropriate use of AMT.[36] A more general approach to the need for AMT is illustrated in Box 191-3.

Trauma

Most trauma studies have addressed air medical use for scene response.[37] Methodological heterogeneity precludes formal meta-analysis of the AMT outcomes data. However, existing data support an estimate of 20 to 35% improvement is survival rates, or the saving of three to six lives (fewer for pediatric patients) per 100 air medical trauma flights.[38-46] As demonstrated by a large 2011 study assessing nearly 75,000 secondary HEMS transports, interfacility air transport of the more seriously injured patient (but not those with lesser severity) is also associated with improved outcomes.[47] Two studies also found improved outcomes with seriously injured patients transported by HEMS while also concluding that stable patients may be transported from outlying hospital to definitive care by ground with equal effect.[47,48] Noting that HEMS represents the *only* modality by which nearly 28% of U.S. residents have timely (within 1 hour) access to level I or level II trauma centers emphasizes the vital role of AMT in care of the injured patient.[49] Studies have also presented data that suggest lack of HEMS benefit for the trauma victim, but these studies represent a minority of works and are limited by confounding factors such as inclusion of transports to nontrauma centers.[50] Whereas caution should be exercised in definitive statements about the criteria for and the value of AMT, and such statements can be interpreted only in light of the overall local environment in which the transport system exists, the clear message from the literature is that HEMS functions best as a part of a comprehensive trauma system and not as an isolated entity.[51-53]

Work in HEMS casts doubt on the supposed logistical advantages of the helicopter itself.[54] Faster times to trauma centers are not required for the accrual of better outcomes. It is true that in some studies, subgroup analyses suggest improved trauma outcomes due to HEMS scene response for the more severely injured.[55] However, studies conducted in regions as disparate as California and The Netherlands demonstrate HEMS mortality benefit but find similar scene–to–trauma center times for ground and air transports.[45,56] It seems clear that for many patients, factors other than speed (such as the provision of advanced levels of care over that provided by ground personnel) are responsible for AMT's benefits.

In terms of specific populations of patients, some studies suggest that most trauma victims transported by air have non–life-threatening injuries.[57] Fortunately, the best large-scale population analysis, of more than 40,000 HEMS transports from the 2007 American College of Surgeons National Trauma Data Bank, clearly demonstrates that HEMS-transported patients are indeed of much higher acuity than ground-transported patients.[37] For example, the median Injury Severity Score of HEMS patients exceeded the commonly used "severe injury" cutoff of 15; HEMS patients also had a 43% rate of intensive care unit admission.[37] If we look more specifically within the trauma population, we find that data from Pennsylvania and California of head injury patients undergoing out-of-hospital intubation demonstrate HEMS-associated improvements in both morbidity and mortality.[58,59] A 2009 study from Italy confirmed the association between HEMS transport and improved head injury outcome as assessed by either mortality or functional endpoints.[60]

AMT is unlikely to improve outcome in those whose injuries are either trivial or grave. However, if the Injury Severity Score is collapsed into five ordinal categories, a significant association between helicopter transport and improved mortality is found in the middle three categories (survival odds ratios range from 2.1 to 2.6). Other work has also found that AMT shows benefit over ground transport only for those more seriously injured patients in both rural and urban environments.[61,62] In all these cases, it remains uncertain if improvements in outcome are related to the provision of improved on-scene care or the integration of HEMS into a comprehensive trauma system as opposed to the air transport itself. Fortunately, even the acknowledged imprecision of triage to HEMS does not preclude "real-world" identification of AMT-associated trauma outcomes benefit. In a 2010 population-based study in Canada, patients were entered into the study if HEMS services were requested, and outcomes were compared between those who actually underwent AMT and those who went

www.ketabpezeshki.com 66485457-66963820

Box 191-3 Criteria for Air Medical Transport (AMT)

Distance to the closest appropriate facility is too great for safe and timely transport by ground ambulance.
Patient's clinical condition requires that the time spent in transport be as short as possible.
Patient's condition is time critical, requiring specific or timely treatment not available at the referring hospital.
Potential for transport delay associated with ground transport is likely to worsen the patient's clinical condition.
Patient requires critical care life support during transport that was not available from the local ground ambulance service.
Patient is located in an area inaccessible to regular ground traffic, impeding ambulance egress or access.
Local ground units are not available for long-distance transport.
Use of local ground transport services would leave the local area without adequate EMS coverage.
For interfacility medical transport, the requesting physician based on his/her best medical judgment and information available at that time of transport determined the need for AMT.
For scene medical transport, the requesting authorized out-of-hospital provider based on applicable policy, his/her best medical judgment and information available at that time of transport determined the need for AMT.

by ground because of the unavailability of HEMS. The study identified a benefit of HEMS, compared with ground transport, of 5.61 more lives saved per 100 transports.[62]

Cardiac Disorders

The ability to study HEMS-related outcomes benefit in acute coronary syndrome is limited by the lack of validated scores that can be used to stratify risk and to predict outcome. Works have noted that helicopter transport extends the geographic referral base of primary angioplasty centers and that outcomes of patients flown from a distance for definitive care equal outcomes of patients presenting primarily to the referral center.[63] AMT systems have been shown to be able to safely transport complicated cardiovascular patients with conditions such as acute coronary syndrome, ST segment elevation myocardial infarction, and aortic aneurysm.[64-67]

Although HEMS could conceivably shorten door to percutaneous coronary intervention (PCI) time by transporting patients with ST segment elevation myocardial infarction rapidly from hospitals without PCI capability to a referral center, in many circumstances the patient will not have angioplasty of the infarct-related vessel performed within the recommended window and would be best served by receiving thrombolytic therapy at the initial hospital and then being transported in a less emergent fashion. AMT might therefore be better used for transport of critical cardiology patients who require emergent care, such as bypass surgery or balloon pump support, that is beyond the capability of the sending hospital.

Stroke

With the advent of time-critical therapy for ischemic stroke, HEMS has played an increasing role in the regionalization of acute neurologic care. Early studies demonstrating safety of transport of post-thrombolysis stroke patients have been complemented by case series illustrating the increasing use of helicopter interfacility transport for stroke.[68,69] Case reports and series have demonstrated the utility of air medical dispatch for primary (scene) transport of patients with strong suspicion of stroke.[70-72] In one region, ground EMS providers were able to identify stroke with accuracy, and helicopter-transported patients composed nearly 25% of the stroke center's thrombolytic volume. The use of strict triage definitions kept inappropriate calls for AMT to acceptably low levels while allowing a significant extension of the geography served by an individual stroke center.[71] Performance measurement programs can monitor the efficacy of the AMT service.[72]

Pregnancy

With appropriate triage, the speed of air transport of the high-risk pregnancy can counterbalance the risk of delivering an infant in an aircraft's confined space.[73,74] Case series demonstrate that high-risk obstetric patients transported by air from distant hospitals have outcomes as good as those of patients presenting primarily to an obstetric referral center.[73,75] Common reasons for obstetric transport include preterm labor and premature rupture of membranes.[76]

Neonates and Children

The use of AMT to extend the geographic reach of neonatal care centers is reported from many settings.[77,78] The most rigorous analysis suggests that long-distance AMT allows infants with medical complications born in remote areas to achieve outcomes equal to those of infants born in urban centers. Although neonates are vulnerable to physiologic deterioration, specialty team air transport is associated with no more derangement in oxygenation and ventilation than is transport by ground vehicle.[77] As in the case of trauma, the question remains if the advantage of AMT is related to the use of air transport or specialty services brought to the patient's side.

Many areas depend on AMT to deliver critically ill or injured children to regional pediatric centers. Although speed of transport may be an important consideration, as with neonates it seems the emphasis is often more on the transport *team* than on the *mode* of transport. Experienced pediatric transfer teams often bring a level of expertise unavailable to the pediatric patient in the outlying hospital and are noted to have fewer adverse events during transport than nonspecialty teams.[79-81] Appropriate training, experience, and competency are essential for those responsible for transport.[82] AMT has been shown to be safe for moving of even the most critical children requiring extracorporeal membrane oxygen support.[83]

EFFICACY AND COST-EFFECTIVENESS

Cost-benefit is an area of increasing focus for AMT. The crux of the problem lies in the inability to precisely identify in a prospective manner which patients will truly benefit from fixed-wing or rotor-wing flight. As a result, in many cases there is little if any guidance regarding when air medical dispatch is indicated.[84] With use of endorsed guidelines (such as those endorsed by the AMPA) for air medical dispatch, EMS regional authorities should collaborate to generate criteria best for their own systems, with constant refinement guided by rigorous use review.[85] Despite this ideal, however, in practice the lack of firm indications and guidelines means that AMT often acts more as a "taxi service" responding to the needs of referring physicians, hospitals, and EMS services

www.ketabpezeshki.com 66485457-66963820

rather than the actual needs of the patient. There is a strong economic argument to be made for maintaining this "looseness" of service, as flight revenues keep AMT services available for those truly in need.

Compared with the cost-benefit ratios of other medical interventions, AMT is well within the accepted range per quality-adjusted life-year saved.[86-88] One Scandinavian study concluded that the benefits of ambulance missions flown by helicopters exceed the costs by a factor of almost six.[89] Another group from the region estimated that HEMS contributes to the cost-effectiveness of primary PCI, and other investigators have demonstrated the favorable cost-effectiveness of helicopter stroke transports.[90,91] However, these results cannot be taken as definitive statements on a global basis, as any cost-benefit calculation is applicable only within the health care environment of the system under study.[92]

Cost-effectiveness determinations are not straightforward. It is difficult to calculate true cost-effectiveness for transports that are not likely to occur (as with high-risk obstetrics cases at risk of precipitous delivery)[73] or that would deliver patients outside critical time windows (as for stroke or cardiac transports) in the absence of AMT.[68,93] Cost-efficiency is also difficult to demonstrate when there are no comparison options (such as transport from coastal islands or locations without road access) or when integrated ground and air transport systems have already become established in ways that effectively prohibit head-to-head comparisons of risks and outcomes (as is true in most of the United States). If we accept that HEMS represents the only mechanism by which more than 80 million U.S. citizens have timely access to mortality-improving high-level trauma center care,[49] it is obvious that some form of air transport is a "must-have" for some EMS regions, and calculations of cost-efficiency fall away in favor of service provision.

Although transport by air is nearly always more expensive than that by ground, the costs of air medical flight should be viewed in contrast with the "real-life" alternative mode of transport. In many cases, and especially where time and distance are significant factors, the total fiscal and opportunity costs of AMT are arguably less expensive than the alternative.[94] Unfortunately, the work of assessing the cost-effectiveness of AMT is complicated by the extremely limited amount of information on the cost-effectiveness of ground-based modes of transport.[95] Experts assessing existing literature have concluded that although the available data do not enable rigorous meta-analysis, most investigations do demonstrate that appropriately used HEMS is cost-effective.

FUTURE OF AIR MEDICAL TRANSPORT

AMT works best and provides the most benefit to the patient when it is integral to and enhances an overall system of out-of-hospital care and interfacility transport and when systems are in place to educate requesting agencies and professionals about the appropriate use of available air and ground resources.

This work has noted that the major challenge within the AMT community is to determine not *whether* but rather *in whom* there is benefit to air medical flight. Currently, the major dilemma facing helicopter transport outcomes researchers is the identification of triage variables that can prospectively (i.e., at the time of transport vehicle selection) guide use of the air medical resource.[84,85,96] It also seems that over time, advances in ground-based EMS and the availability of critical care ground ambulances for interfacility transports are beginning to offset many of the assumed benefits of AMT. Nonetheless, the regionalization of specialty services, development of new therapies that are highly time sensitive, and inflexible geography mean that there will always be a role for AMT in emergency care.

Chapter 192

Tactical Emergency Medical Support and Urban Search and Rescue

Richard B. Schwartz and John G. McManus

TACTICAL EMERGENCY MEDICAL SUPPORT

Perspective

Law enforcement agencies in the 21st century face an increase in terrorist threats and new challenges, including organized opposing forces, military-type weapons, direct fire, hostage and barricade situations, and potential toxic hazards. As these threats have increased, so has the recognition of the need for integrated medical support of tactical operations.[1] Tactical emergency medical support (TEMS) is the specialty of emergency medical services (EMS) established to maintain safety, health, and welfare for combat medical units and special operations civilian law enforcement units, such as special weapons and tactics (SWAT) teams, hostage rescue teams, and special emergency rescue teams.[1] These specially trained teams are composed of highly trained and specially equipped personnel who are tasked with mitigating and responding to many different high-risk situations.[2-5] Events such as the World Trade Center bombings and hurricane Katrina have demonstrated the need for many nonhospital health care personnel to use some of these current military out-of-hospital medical strategies.

Tactical Medical History

The principles of TEMS have largely been developed through lessons learned from military conflicts. Civilian TEMS structure most closely emulates the medical support structure of military special operations units, such as Army Special Forces, Navy Seals, Army Rangers, and Air Force Pararescuemen. These small, unique tactical units frequently operate outside the normal realm of military operations remote from dedicated medical resources, often for long periods.

In the civilian setting, snipers, mass demonstrations, riots, and fire bombings gained notoriety as new forms of urban conflict in the United States during the late 1960s and early 1970s, which led to the formation of the first SWAT unit. In 1996, there were more than 5000 SWAT teams in the United States supporting local, state, and federal agencies. Essentially today, more than 90% of municipalities with a population greater than 50,000 have a SWAT team.[5] With the evolution of these specialized law enforcement tactical teams, the need for military-style EMS support began to emerge.

Because of the dangerous environment, SWAT team members are at high risk for injury, with a casualty rate of 33 injuries per 1000 officer missions. Suspects are injured at the rate of 18.9 injuries per 1000 officer missions, and bystanders are injured at the rate of 3.2 per 1000 officer missions. It was recognized that traditional EMS providers were not properly trained or equipped to enter these unique and sometimes remote austere environments to care for casualties. In fact, basic EMS training still emphasizes that personnel should wait until the "scene is safe" before rendering medical care to patients. Past incidents, such as shootings at Columbine High School in Littleton, Colorado, Ruby Ridge in Idaho, the University of Texas in Austin, and the Mormon Library in Salt Lake City, proved that sequestering of medical personnel far from the area of operations leads to delays in definitive trauma care, with potentially higher morbidity and mortality.[6] The tactical environment necessitates that the medical provider possess a unique training and skill subset to use a different set of field assessment and treatment priorities and strategies for monitoring and sustaining health maintenance. Provision of tactical medical care has now become an integral part of preplanning for federal, state, and local tactical teams in response from lessons learned.[1,2]

The principles of tactical combat casualty care (TCCC) have been refined and now applied on today's battlefield[7-10] as well as in most civilian TEMS teams.[1,11-13] TCCC is a set of guidelines that aim to prevent further casualties, to accomplish the tactical mission, to save the maximum number of lives, and to minimize morbidity of the injured. These guidelines are developed by the Committee on Tactical Combat Casualty Care, which falls under the U.S. Defense Health Board. The TCCC guidelines are based on treatment of the leading preventable causes of combat death, which include hemorrhage from a compressible site, tension pneumothorax, and airway compromise.[11-13] In the most recent TCCC guidelines, attention to hypothermia prevention, intravenous access, improved en route care, closed head injury, and pain management techniques are also addressed.[11] Whereas TCCC is widely accepted in the military combat setting and has largely been extrapolated to the civilian environment, there are some data that question the applicability of TCCC to the civilian environment.[12]

Goals of Tactical Emergency Medical Support

In the early years of development, TEMS focus was on care and evacuation of wounded. This role has now evolved to include more emphasis on mission planning, primary care, preventive medicine, and emergency care of illness and injury. Although the primary goal of TEMS is to enhance the law enforcement mission, the tactical medical role involves a continuum of care that includes maintenance of team health; reconnaissance of environmental and situational aspects of the mission; coordination of local emergency medical support; creation of evacuation plan and routes; and assessment of future medical needs of the team, perpetrators, bystanders, and possible hostages.[1,14] Implementation of

www.ketabpezeshki.com 66485457-66963820

Box 192-1 Goals of Tactical Emergency Medical Support

Enhance mission accomplishment
Prepare medical threat assessment
Monitor the medical effects of environmental conditions
Reduce death, injury and illness, and related effects among team members, innocents, and perpetrators
Reduce lost work time
Maintain good team morale
Maintain health of team and provide preventive medicine
Coordinate with surrounding agencies and hospitals
Decrease liability
Possess basic forensic knowledge and crime scene preservation

an effective tactical medical support program is directed at achievement of several important goals (Box 192-1).

Tactical Team Structure, Training, and Integrated Medical Support

SWAT team and combat TEMS structure and size vary throughout the United States according to location and purpose. The typical team is composed of assault teams, which make initial contact with suspects, and arrest teams, which support the assault team. There are also rescue teams, backup teams, and hostage and negotiation teams. A unit commander supervises the operation from a command post.[2]

The TEMS component of a tactical unit, like team structure, varies widely throughout the United States. Some SWAT teams use "standby" EMS personnel, whereas others have physician-only TEMS providers. Much like the military Special Forces, many civilian tactical law enforcement agencies are now integrating medical support into the tactical team to enhance mission success.[2]

Although it is not ideal, the minimal medical coverage at a tactical location should be the use of standby civilian EMS personnel in a predetermined location. The standby EMS personnel treat casualties that are brought to them but are unable to assist in medical preplanning or inner perimeter rescue. This minimal medical support for tactical missions may be inadequate for some missions, given the high degree of potential injury and delay in definitive care.

Law enforcement agencies using integrated medical support have varying medical qualifications. The use of an emergency medical technician for medical coverage has the advantage of availability and modest cost. Medical directors may be able to train basic providers with an enhanced skill set to provide appropriate medical care for tactical support. However, the increased skill set possessed by advanced nonhospital providers makes them favorable in a TEMS environment.[2,11] In a small number of jurisdictions, emergency physicians and residents provide medical oversight for TEMS units and are also deployed as medical operators in the tactical environment.[2,4] Although physician providers offer a broader scope of practice and do not require direct medical control, they usually have limited out-of-hospital experience and also require tactical training. In addition, as the law enforcement mission takes on additional roles overseas, there is a growing need for forward surgical teams similar to military forward surgical teams that can function in remote areas. The Georgia Health Sciences University has developed one such surgical resuscitation team that has been deployed in support of law enforcement operations (www.georgiahealth.edu/ems/COM/Tactical/).

Training Issues

The tactical environment is different from the traditional EMS environment. Traditional EMS doctrine taught personnel to ensure that the scene is "safe" before attempting to render care.[11] This principle is not possible in some tactical situations. Tactical training needs to take into account team tactics and movement; cover and concealment; equipment issues; nuclear, biologic, and chemical training; rappelling; weapons familiarity; and noise and light discipline training.[2] Also, routine training needs to be done in basic rescue tactics, tactical room entries, open area rescues and tactics, movement under fire, cover and concealment, officer down drills, and, in some systems, firearm training (Fig. 192-1). Furthermore, many teams are now training all team members in medical management for lifesaving interventions.

Figure 192-1. Special response team training for the extraction of an injured suspect. Note that the suspect is secured with handcuffs to ensure the safety of the team and bystanders. (Photograph by Richard Schwartz.)

In the military and operational environments, there is a significant increase in the number of penetrating traumatic injuries (e.g., gunshot, fragmentary, and blast propellant wounds).[13-15] Because of the increased complexity and number of combat casualties and the possibility that civilian TEMS providers may be exposed to such, additional training and knowledge of the TCCC guidelines are important for the operational and tactical medic. Although advanced trauma life support may be applicable to the emergency department management of trauma patients in both civilian and military hospitals, it was not created for combat or tactical out-of-hospital medicine.[11,16] The three goals of TCCC are to treat the casualty, to prevent additional casualties, and to complete the mission.[6] TCCC is divided into three distinct phases to provide the correct medical interventions at the correct time in the continuum of out-of-hospital care (Box 192-2).

www.ketabpezeshki.com 66485457-66963820

Box 192-2 Phases of Tactical Combat Care

Care under fire
Tactical field care
Casualty evacuation care

Care under Fire. In terms of medical delivery in the civilian tactical environment, the area is usually divided into three zones—cold, warm, and hot. These zones are based on tactical environment, threat level, and treatment options, which are based on a risk-benefit ratio relative to the medical provider and patient. The cold zone is a safe environment with no threat to injury. This zone is outside the inner perimeter, and regular EMS treatment principles usually apply. In the warm zone, threat is not considered immediate but still exists. Finally, the hot zone is characterized by possible direct exposure to hostile fire.

As such, *care under fire* refers to care being rendered in the hot zone. In this zone, the medic and casualty are under direct effective hostile fire. Care in this phase is limited but not nonexistent. When care may be rendered, airway management, the first medical priority in routine out-of-hospital medicine, is best deferred until the tactical field care phase because of difficulty in maintaining the airway during evacuation under direct fire. Also, cardiopulmonary resuscitation and cervical spine immobilization have little or no role in the treatment of penetrating injuries in this phase and are not a priority in the combat environment.[16-18] Recommended care is limited to mitigation of threat (i.e., suppressive fire), placement of the casualty in rescue position if possible, tourniquet use, and evacuation of the casualty to a safer "zone" or "phase" of care if possible.

Because uncontrolled extremity hemorrhage was the leading cause of preventable battlefield death, a large portion of research and training was directed toward hemorrhage control.[13,19] During the current conflict in Iraq and Afghanistan, newer tourniquets, hemostatic agents, and dressings and intravenous therapies have been developed, researched, and fielded by the military with unprecedented speed, reducing morbidity and mortality for compressible, extremity hemorrhage.[19] During the care under fire phase, extremity hemorrhage control is ideally gained through the use of tourniquets. Although shunned for many years, tourniquets have re-emerged as the standard of care in this environment because of low complication rates, ease of use, rapid application, and effectiveness in stopping blood loss.[6,19-24] Improvised tourniquets such as rubber surgical tubing are not recommended and should not be used unless commercial tourniquets are unavailable.[23] Several studies have found that tourniquet use on the current battlefield has not resulted in increased limb loss or permanent disability even among patients thought to have had tourniquets applied unnecessarily and has resulted in a reduction in mortality with application before onset of shock and in the prehospital environment.[6,19,21]

Many types of extremity tourniquets are presently available for both civilian and military use. Two tourniquets currently used on today's battlefield by the U.S. Army are the Combat Application Tourniquet (C-A-T) and the Special Operations Forces Tactical Tourniquet (SOFT-T).[19,24] On the basis of current literature, both the U.S. and the Israeli military, the International Committee of the Red Cross, and civilian agencies in the United States have embraced tourniquets as an initial hemorrhage control option during the care under fire phase as well as for uncontrolled extremity hemorrhage to achieve rapid control of bleeding.[11,21] The current TCCC recommendation is for liberal use of appropriate tourniquets for uncontrolled extremity hemorrhage in the tactical environment.

Tactical Field Care. The second phase of care, tactical field care, is medical treatment rendered in the warm zone. This phase consists of medical care that is delivered while the medic and casualty are still under threat of injury but not under direct, effective hostile fire. Simply by dragging a casualty 5 feet around the corner of a building could transition the medic from care under fire to tactical field care. Care in this phase focuses on several areas that have been shown to increase morbidity and mortality in tactical environments if they are not addressed.[17] Airway establishment and maintenance are first addressed in this phase of treatment. Next, breathing issues, such as tension pneumothorax and open pneumothorax (sucking chest wound), may need to be addressed in this phase of care. Circulatory issues, such as tourniquet replacement with direct pressure dressings or advanced hemostatic agents and fluid therapy, are then addressed. Intravenous or interosseous access needs to be established. Hypothermia prevention, adequate analgesia, prophylactic antibiotics, and appropriate use of cardiopulmonary resuscitation are also addressed in this phase.[13]

Advanced Hemostatic Agents. The ideal out-of-hospital hemostatic agent ideally would require little training; be nonperishable, durable, flexible, and inexpensive; adhere to the wound only; pose no direct risk of disease; not induce a tissue reaction; and effectively control hemorrhage from arterial, venous, and soft tissue bleeding. There is no single ideal advanced hemostatic agent that currently meets all of these criteria for either military or civilian use. However, many hemostatic agents have been used successfully for uncontrolled hemorrhage on today's battlefield and have contributed to reduced morbidity and mortality in penetrating combat trauma.[25-30]

Although many hemostatic agents are approved by the U.S. Food and Drug Administration (FDA) and have been used in both the civilian and military environments, the agent currently recommended by the Committee on Tactical Combat Casualty Care is Combat Gauze. Combat Gauze, a mineral-based dressing containing a kaolin coating, is thought to function by activation of clotting factors. More recent dressings with fine-mesh poly-rayon gauze and chitosan impregnation have been demonstrated to be at least as efficacious as Combat Gauze in a porcine model.[29]

Point Compression Devices and Trunk Tourniquets. The rapid development and fielding of tourniquets and hemostatic agents on today's battlefield have greatly reduced morbidity and mortality from previously uncontrolled hemorrhage, particularly from isolated extremity injuries. However, exsanguination-related mortality still exists. Anatomic areas that are not amenable to tourniquet application, referred to as junctional areas (i.e., neck, groin, axilla), have now become the focus of hemostatic research.[31] In fact, the current combat epidemiology reports that junctional injury and bleeding is now the most common "potentially survivable" combat injury. Because junctional injuries continue to be a challenge to hemorrhage control in the tactical setting, newer devices are being developed to control these injuries in the field setting to allow the casualty time to have surgical control in an operative setting.[30-32] One of the newer devices has been approved by the FDA for control of proximal femoral artery injuries, the Combat Ready Clamp (CRoC, Combat Medical Systems). This is a large C-clamp that is placed over the femoral vessels to provide direct compression. Another device under development is the abdominal aortic tourniquet, which is a pneumatic tourniquet that externally compresses and occludes the abdominal aorta at its bifurcation. This device has been shown to occlude the abdominal aorta in a pig model for up to 60 minutes without evidence of bowel ischemia or hyperkalemia and is pending FDA approval for the indication of hemorrhage control of proximal femoral and pelvic vascular injuries.[33]

Tension Pneumothorax. Another leading cause of potentially preventable battlefield death is tension pneumothorax, accounting for up to 3 or 4% of all fatal injuries.[14,34] McPherson and

www.ketabpezeshki.com 66485457-66963820

colleagues[34] studied radiologic and autopsy examinations of 978 fatalities from the Vietnam conflict; 15 of the casualties with identified tension pneumothorax lived long enough to be treated by a medic, but none underwent needle decompression and all of them died.

Although needle thoracostomy is a controversial procedure in the civilian trauma setting for adults, current TCCC guidelines recommend consideration of needle decompression in casualties with chest trauma and progressing respiratory distress.[17,34] The current recommendation is to use a 14-gauge or larger 3.25-inch needle. This recommendation is based on computed tomography evaluation of the chest wall, which indicted that a standard 2.0-inch needle would penetrate the pleural space in only 75% of causalities.[35]

Airway Management. Airway compromise is also a potentially preventable cause of battlefield death.[36] Historically, airway compromise is responsible for approximately 1% of fatal injuries on the battlefield and is due to facial or neck trauma causing obstruction. These data are consistent with a more recent review of fatal airway injuries from Operation Enduring Freedom and Operation Iraqi Freedom, which demonstrated an airway fatality rate of 1.8%, with 100% having penetrating injuries to the face or neck.[36]

Initially, in an unconscious patient with intact upper airway anatomy at risk for airway compromise, the recovery position and minimally invasive adjuncts, such as the nasopharyngeal airway and the oropharyngeal airway, are emphasized. However, given the high incidence of trauma as a cause of airway obstruction, the cricothyroidotomy is taught as the definitive airway management technique on the battlefield if simple maneuvers fail. Traditional methods providing ventilation, such as endotracheal intubation, the laryngeal mask airway, the Combitube, and the King laryngeal tube airway, may not be as feasible in tactical situations. The initial training requirements as well as maintenance issues for these skills for all military medics are simply not practical. Furthermore, use of white light required for laryngoscopy may draw enemy fire on the battlefield. Finally, on the basis of the best available data, many patients needing airway management are likely to have disrupted upper airway anatomy, for which these skills would not be successful and cricothyroidotomy would be indicated. A recent review of battlefield fatalities demonstrated a high failure rate of cricothyroidotomy (5/5) and raises the question of the most appropriate algorithm for airway management in the tactical setting.[36]

Intravenous Access and Fluid Resuscitation. The tactical environment often makes intravenous access difficult, and alternative techniques and routes may be needed to establish access.[17,37-39] Medics therefore are trained to obtain intraosseous access for fluid administration if intravenous access is not obtainable or timely. Several newer intraosseous devices are used in both civilian and combat tactical environments, including the EZ-IO, the Pyng FAST1 sternal intraosseous infusion device, and the Bone Injection Gun, with great success and little morbidity.[40,41]

The current recommendations for intravenous resuscitation on the battlefield focus only on those patients with signs of hemorrhagic shock. Because the majority of combat casualties present with non–life-threatening penetrating extremity injuries, the number of casualties actually requiring intravenous fluids in the field is few. In fact, fluids are encouraged to be taken orally if the casualty is conscious and can tolerate drinking.[17] If fluids are necessary, TCCC guidelines recommend an infusion of 500 mL of Hextend, followed by an additional 500 mL in 30 minutes if shock is still present.[17,31]

Hextend, a colloid, is the recommended fluid of choice over crystalloid solutions. Hextend remains in the intravascular space longer, requiring significantly less volume than crystalloids. These factors are critical when supplies must be carried in the medic's pack. Future battlefield resuscitation strategies may include hypertonic saline or combinations of hypertonic solutions and colloids. A growing scientific literature supports this "hypotensive resuscitation" strategy.[31,42,43]

Hypothermia Management. Hypothermia has been well recognized as an independent factor contributing to increased morbidity and mortality in trauma patients. Studies have shown hypothermia to be associated with increases in acidosis, coagulopathy, multiple organ failure, length of hospital stay, and mortality.[44,45] In the austere environment, prolonged out-of-hospital times, cold fluid administration, and environmental factors affect the patient's core temperature, as does bleeding that results in hypoperfusion, which alters the body's thermoregulation and results in hypothermia.

TCCC emphasizes prevention of hypothermia (<34°C) in patients with penetrating trauma. Prevention of heat loss should start as soon as possible after wounding. This is optimally accomplished in a layered manner. Several new devices are being tested and fielded in the combat out-of-hospital setting for hypothermia prevention to maintain casualty core temperature as well as to administer warmed fluids.[46]

Analgesia. The tactical environment exacerbates the typical challenges found in treatment of acute pain and has the additional obstacles of a lack of supplies and equipment, delayed or prolonged evacuation times and distances, devastating injuries, provider inexperience, and dangerous tactical situations.[47,48] Studies have shown an increase in the incidence of chronic pain and posttraumatic stress disorder (PTSD) with failure to recognize and to treat acute pain appropriately as well as a reduction in PTSD incidence when pain is adequately managed, particularly with early use of ketamine.[49,50]

Finally, other newer analgesic agents and routes of delivery are being used on the battlefield. Oral transmucosal fentanyl citrate has been found to relieve moderate to severe pain on the battlefield and is currently carried by many Special Forces medics.[51] Also, ketamine has been used successfully as an out-of-hospital analgesic in the civilian and combat setting.[52] Ketamine in subanesthetic doses is an almost ideal analgesic because of its profound pain relief, its role in prevention of opioid hyperanalgesia, and its large margin of safety.[53]

Triage and Advanced Vital Signs. It has been hypothesized that some trauma deaths may be preventable if the severity of blood loss can be recognized earlier during out-of-hospital medical care. It is obviously better to prevent hemodynamic compromise (i.e., shock) than to treat it once it has already begun to occur.

In an attempt to provide new possibilities for more efficient algorithms that may assist in determination of treatment and evacuation priorities for patients with unrecognized hypovolemia and early shock, new and more accurate noninvasive indicators of the underlying physiologic status in trauma patients who have initial normal systolic blood pressure and Glasgow Coma Scale scores have been investigated and implemented in current combat operations.[54,55] Some of these indicators of hypovolemia include derived physiologic variables (e.g., shock index, pulse pressure, and field trauma score)[55-57] and continuous "real-time" variables (e.g., electrocardiogram R wave amplitude and heart rate variability).[58,59] The National Association of EMS Physicians, with funding from the Centers for Disease Control and Prevention, has led an effort to standardize mass casualty triage. Through this project, a new triage system has been developed that uses the principles of TCCC. This system is called SALT (sort, assess, lifesaving interventions, and treatment or transport) and has been endorsed by multiple organizations, including the American College of Emergency Physicians.[60]

Combat Casualty Evacuation Care. Combat casualty evacuation care is the third phase of care. It is rendered to the casualty in the cold zone and while the casualty is evacuated to definitive medical

www.ketabpezeshki.com 66485457-66963820

Figure 192-2. Combat casualty evacuation care is usually provided by aeromedical transport or advanced life support ambulance in the civilian setting. (Photograph courtesy the *Augusta Chronicle* and Andrew Davis Tucker.)

care. Care now begins to closely approximate traditional civilian field medical care and includes advanced life support en route to the receiving facility, often a trauma center (Fig. 192-2).[11]

Intravenous Hemostatic Agents. In the future, optimal out-of-hospital hemorrhage control in the combat environment may also involve use of intravenous agents for replacement and coagulation principles. In selected combat nonhospital settings, tranexamic acid, hemoglobin substitutes, lyophilized plasma, freeze-dried blood, and component products are currently being developed or evaluated for appropriate use.[42,61] In this phase of care, on the basis of recent literature, the TCCC currently recommends that tranexamic acid be administered as 1 g in 100 mL of normal saline or lactated Ringer's solution as soon as possible, but not later than 3 hours after injury, if the casualty has major hemorrhage or is probably going to require a significant transfusion.[61,62]

TEMS Environment

Training

Practicing effective medical care in the tactical environment requires TEMS personnel to be well educated, trained, and equipped. Integrated "team" training allows the medical support members to understand their roles and to learn all aspects of tactical law enforcement operations and fundamentals on how to approach the tactical medical arena. TEMS competency-based guidelines have recently been published to guide the development of TEMS training curricula.[1] A project has been initiated by the Centers for Disease Control and Prevention to develop a nationally standardized curriculum for tactical medicine training. This project, using an expert panel and review of the scientific literature, refined the previously published outcome competencies and developed terminal and enabling training objectives to the competencies. The results of this project will be published as a national TEMS curriculum. In addition, training curricula have been established, such as the National Tactical Officers Association's Specialized Tactics for Operational Rescue and Medicine (STORM) for medics, operators, medical directors, and team commanders. These courses are based on the national TEMS curriculum and use the trainer methodology.

Equipment

The medical equipment selected and carried by TEMS providers varies and is based on usage, size, weight, budget, training, experience, and mission type. Use of conventional EMS medications and equipment with bright markings and color coding is often discouraged in the tactical environment to maintain concealment.

Remote Patient Assessment

Remote patient assessment is another function of TEMS. Medical personnel assess the injured person from a distance with use of binoculars, gun scopes, night vision goggles, cameras, and microwave radar motion detectors.

Hazardous Materials

Incidents involving clandestine drug laboratories and weapons of mass destruction are also considerations in a TEMS environment. Rapid decontamination must be taught and practiced by tactical teams because adequate decontamination is usually not available in the inner perimeter.[63]

Forensic Science

Basic knowledge of forensic science is important for recognition and preservation of evidentiary items. Documentation of wound and blood patterns should be done. All evidence should be collected appropriately and the chain of custody maintained.[64]

Medical Threat Assessment

Medical threat assessment (MTA) is an important part of medical planning and should be integrated into the tactical operation.[2] The MTA considers the potential medical threats that may confront the team during the tactical operations and develops the plan to mitigate and to respond to the threats. Once the MTA is complete, a plan is then developed on the basis of the medical intelligence to address each possible situation, with the realization that the plan may change as the mission evolves.

Preventive Medicine and Force Health Protection

The maintenance of the tactical team's health is an important aspect of a TEMS program. Poor health has been shown to directly correlate with poor job performance and mission failure.

Liability

Because special operations lend themselves to high litigation and possible disability, TEMS providers need to ensure that they have proper malpractice and disability coverage.[2,65]

URBAN SEARCH AND RESCUE

It was hard to breathe. The air was thick and choking. It looked as though black snow had fallen, covering everything.

It was as dark as a tunnel and the air was as thick as soup. Despite repeatedly scooping chunks of dust and debris from my mouth and nostrils, I inhaled and swallowed large quantities.

www.ketabpezeshki.com 66485457-66963820

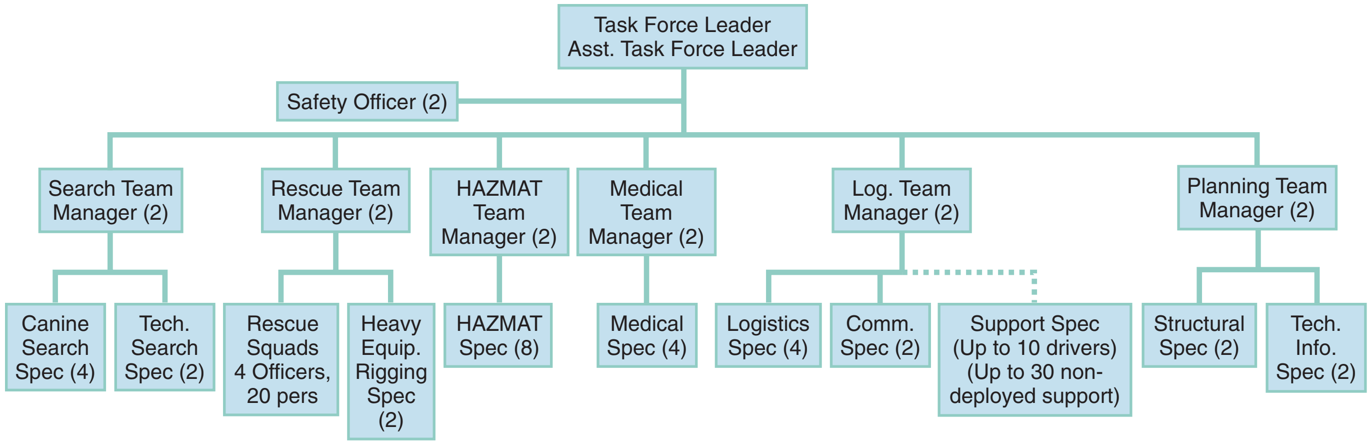

Figure 192-3. Structure of a FEMA US&R team.

It took an hour to wash off the layers of dust, which by now had become like a layer of concrete.

Drs. Kelly and Prezant, New York City Fire Department, during the September 11, 2001, terrorist attacks.

Perspective

Urban search and rescue (US&R) is the science of responding to, locating, reaching, medically treating, and safely extricating victims entrapped by collapsed structures. US&R is a "multihazard" discipline because it may be needed in a variety of emergencies and disasters, including wilderness mishaps, natural disasters such as the recent earthquakes in Haiti and Japan, and man-made disasters (e.g., terrorist attacks, building and structure collapse, hazardous materials spills).[65,66] Federal activation of US&R teams occurs when local and state resources have been overwhelmed and there has been a request from a state governor to the President for the activation of federal response assets. In addition, in catastrophic events, the activation of military assets may be required to assist in a support role of other local, state, and federal assets.[66,67] For responding resources to be effective, they should be highly trained, quickly deployable, mobile, and self-sufficient.

Components and Structure of an Urban Search and Rescue Team

The responding team must mobilize quickly to accomplish its objectives and should not place additional demands on the already stressed infrastructure. Figure 192-3 shows the organizational structure of a Federal Emergency Management Agency (FEMA) US&R team.[66] There are 28 FEMA US&R task forces throughout the continental United States that are trained and equipped to handle structural collapse. FEMA will deploy the three closest task forces within 6 hours of notification of an emergency. Each task force consists of two 31-person teams, four canines, and a comprehensive equipment cache. US&R task force members work in four areas of specialization: search, to find victims trapped after a disaster; rescue, which includes safely digging victims out of tons of collapsed concrete and metal; technical, made up of structural specialists who make rescues safe for the rescuers; and medical, which cares for the victims before and after a rescue.

An effective US&R team needs both properly trained personnel and appropriate equipment. The equipment cache should allow the task force to be totally self-sufficient for the first 72 hours and to be capable of 24-hour operation for 10 days.[65,67] The FEMA equipment cache is divided into five groups: rescue equipment, medical equipment, technical equipment, communications equipment, and logistics equipment. The medical equipment cache was designed to treat the unique medical needs of trapped victims as well as the medical needs of the team. The medical cache contains enough supplies to handle 10 critical cases, 15 moderate cases, and 25 minor cases. The cost of the entire cache is approximately $2 million.[66,67]

Coordination and cooperation with local resources and other teams are critical.[68] The US&R team is integrated into the Incident Command System at the disaster.

The search team is responsible for development and implementation of a plan to search the area for victims. The search team can be subdivided into two teams, a canine search team and a technical search team. The canine team uses specially trained dogs to locate trapped victims. The technical team uses specialized microphones, listening devices, cameras, and fiberoptic devices to locate victims in confined spaces. The search team is responsible for locating victims and identifying probable areas where victims may be found.

The rescue team is composed of rescue specialists. Once a victim or potential victim is located, the rescue team is responsible for breaching the area and creating a safe entrance to and exit from the victim's position.

The technical team is composed of various specialists, including structural specialists, hazardous materials specialists, heavy rigging and equipment specialists, technical information specialists, and communications specialists.[68] These specialists work collaboratively to ensure a safe and efficient operation.

The logistics team is responsible for all the equipment needs, including inventory, issuing, and record keeping.[68]

Finally, the medical component is composed of medical personnel who are responsible for the medical needs of both the task force personnel and the victims. Typically, the medical personnel are emergency physicians and paramedics.[68,69]

Medical Team Operations in Urban Search and Rescue

A number of unique considerations must be addressed for US&R. As with TEMS, team physicians must realize that they will be operating outside of their usual environment and that they are not in charge overall. Typically, the physician on the team works with the team leader and the managers of the other components. To do this efficiently, the physician should be familiar with the capabilities and training of all the members on the team and the Incident Command System. Cross-training of team members is ideal.[68-70]

Box 192-3 Medical Intelligence Gathering before Deployment

- Type of disaster and predicted numbers and types of potential victims
- Capabilities of the team to deal with the medical aspects of the situation, including dealing with injured team members
- Local emergency department's level of functioning; trauma center status and location
- Local EMS resources
- Location of planned triage staging area
- Communications with local resources (e.g., EMS, police, emergency departments, fire and rescue)
- Weather, environment, or hazardous materials issues
- Availability of other resources (military, NDMS, DMAT)

DMAT, disaster medical assistance team; *EMS,* emergency medical services; *NDMS,* National Disaster Medical System.

Medical Team Tasks

Predeployment. The job of the medical team in the predeployment phase is to ensure that the entire team is fit and functional for deployment and that the medical equipment cache is organized and up-to-date.[69] The perceived medical threats in the deployed area must also be addressed (e.g., endemic disease, water contamination, insect threats, existing medical support). A family and communication support system should also be set up before the deployment.

Deployment. The medical team is responsible for much more than just treatment of the victims. Medical intelligence information needs to be collected and addressed (Box 192-3). A plan is required for transfer and transport of victims and for fatality management.

The medical action plan is critical for ensuring smooth operations and should be updated as conditions or knowledge changes.[66,68,69] The medical component of a US&R team needs to be able to provide care for its own team members, whose needs may exceed those of the victims. The medical team also needs to assess the adequacy of team members' rest and sleep and the psychological effects of the situation.[68,69] In addition, the US&R medical assets must be integrated with the overall medical response that is guided under Emergency Support Function #8, Public Health and Medical Services. This includes integration with existing medical resources, disaster medical assistance teams, TEMS resources, military resources, and public health. If there is a canine search component, the medical team should receive some sort of basic veterinary training before deployment.[68,69]

Confined Space Issues

A confined space is defined as any space with limited access and ventilation. The physician and medical team must be prepared to work in this setting during a deployment and should be aware of issues related to team and victim safety, air purification, and structural dynamics related to collapse or impending collapse.[68-70] Medical providers may be asked for input on ceasing of rescue operations based on the likelihood of finding survivors. Evidence from the 2010 Haitian earthquake indicates that this decision should be based on the individual characteristics of the event and should not rely on predefined time frames to determine ceasing of search and rescue operations.[71]

Specific Disorders in Urban Search and Rescue

US&R teams will typically be responding to the aftermath of earthquakes, collapsed structures, terrorist bombings, hurricanes, and other natural and man-made disasters.[68,71] Reviews of the literature have identified the types of medical problems and conditions that might be encountered.[65,66,69,70] Most of the medical conditions are those encountered in the emergency department and are handled similarly. The following clinical problems occur with much greater frequency in the US&R environment: crush syndrome, compartment syndrome, particulate inhalation, hazardous materials exposures, and blast injuries.[69] Since the terrorist attacks of September 11, 2001, there has also been an emphasis on preparing the US&R teams for the medical response to weapons of mass destruction.

Crush Injury and Crush Syndrome

Compartment syndrome is defined as crush injury caused by swelling of tissue inside the confining fibrous sheath of a muscle compartment, which can cause further destruction of the intracompartment muscle and nerves. Compartment syndrome is discussed in Chapter 49.

Crush syndrome is defined as the systemic manifestations caused by crushed muscle tissue. This typically occurs when blood flow is restored to the crushed tissue and the toxins are released systemically. It is estimated that 3 to 20% of earthquake victims and up to 40% of survivors of multistory building collapses will have crush syndrome.[72] Early hydration of the victim in the rubble before, during, and after extrication can lessen the renal effects of crush syndrome.

The amount of time required for crush syndrome to develop depends on both the amount of pressure and patient factors. It can occur within 1 hour if the pressure is severe, but it usually takes 4 to 6 hours to develop.

Pathophysiology of Crush Syndrome. The cause of muscle injury in crush injury is not fully understood and controversial. The intracellular contents of the cell include lactic acid, potassium, myoglobin, uric acid, enzymes, leukotrienes, thromboxane, phosphate, and others. There is also increased capillary permeability. This can lead to edema and third spacing of fluid.[72] These effects occur locally until the tissue is released and reperfused. This is why victims can be trapped for days with severe crush injury and appear stable when they are reached by rescuers only to deteriorate soon after being rescued. There are reports of patients going into cardiac arrest soon after rescue.[73,74] When the crushed area is released, there is a release of all the intracellular contents that have been building up locally into the systemic circulation, causing systemic symptoms. The major causes of early death due to crush syndrome are hypovolemia due to third spacing of fluid, dysrhythmias due to severe metabolic acidosis, and hyperkalemia. Delayed causes of death include renal failure, acute respiratory distress syndrome, sepsis, ischemic organ injury, disseminated intravascular coagulopathy, and electrolyte disturbances.[72,73]

Management of Crush Syndrome. Early aggressive therapy is essential for prevention of crush syndrome, and it should begin before extrication.[72-74] All victims who have an obvious crush injury or are immobilized for 4 hours or more should be considered to have crush injury. The severity of the crush syndrome may be related to the number of extremities with crush injury. In a Japanese study of earthquake victims, the incidence of acute renal failure due to crush syndrome was 50% for one involved extremity, 75% for two involved extremities, and 100% for three or more involved extremities. Once a victim is located, the medical component needs to be actively involved with the rescue process and begin treatment before extrication. Cardiovascular instability is commonly seen in crush syndrome. As extrication is being done, continuous cardiac monitoring is recommended. Adequate hydration is recommended along with the usual management of hyperkalemia (e.g., insulin or glucose, ion exchange resins, beta-agonists, and dialysis). The current guidelines taught in the FEMA medical

Figure 192-4. Massive amounts of dust and contaminants can exacerbate existing medical conditions, such as asthma and chronic obstructive pulmonary disease, during US&R operations.

specialists course recommend intravenous calcium only for arrhythmias that do not respond to other measures or when there is a documented severe hypocalcemia.[69] It has been suggested that an average-size adult may require up to 12 L/day of fluids to sustain a forced diuresis of 8 L/day to prevent renal complications. Continued monitoring of the patient's vital signs, hydration status, and urine output should be done to guide fluid administration until more invasive monitoring is available.[70] Alkalinization of the urine to prevent renal failure has been recommended in crush syndrome but has not been subjected to proper study, and the effects of the alkalinization, if any, are impossible to separate from those of the volume fluid used. Rhabdomyolysis and its relationship to renal failure are discussed in Chapter 127.

Other Medical Problems in Urban Search and Rescue

Another unique medical problem in US&R is dust and airway contamination. During earthquakes and building collapses, a tremendous amount of dust is released into the air. During the first 48 hours of rescue efforts at the World Trade Center, 90% of the 10,116 New York City Fire Department rescue workers evaluated at the site reported an acute cough often accompanied by nasal congestion, chest tightness, or chest burning, but only three required hospitalization for respiratory symptoms (Fig. 192-4). A cough was eventually found in 1561 (29.1%) firefighters at baseline and 1186 (22.1%) at follow-up, including 559 with delayed onset.[75] The victim of a collapsed structure should be assumed to have some sort of dust contamination. Evaluate the airway for any evidence of burns or hazardous materials exposure. During the extrication process, monitor the patient's airway and be prepared for deterioration. If intubation is being considered, it is better to do it early before edema obstructs the airway, making the procedure more difficult. Medical management of the victim reached after prolonged entrapment is different from that in the typical trauma setting. The "scoop and run" approach of the trauma patient is not always appropriate or possible.

Chemical, explosive, and radiologic agents represent potential threats to the US&R team. Hazardous materials may be released from many sources, such as manufacturing plants or transportation vehicles. Explosion and fires from disrupted gas lines or other flammable and explosive gases and liquids present a significant hazard. Radiation is a danger that may threaten search and rescue operations as demonstrated by the Fukushima nuclear reactor radiation leak after the recent earthquake in Japan. US&R team members should work closely with hazardous materials response teams when responding to these threats.

Hypothermia may also be an issue for patients subjected to environmental conditions. Stabilization, extrication, and ongoing treatment should also be directed at the prevention or reversal of hypothermia, as discussed previously.

KEY CONCEPTS

- The hostile environment that is intrinsic to combat and urban SWAT team operations requires specialized training and planning for medical personnel.
- Determination of medical capability for the hot, warm, and cold zones of a conflict area requires evaluation of local characteristics, the nature of the threat, team safety, and community resources.
- US&R teams have many integrated components. Typically, the medical component is the smallest part of the team but has some of the greatest responsibilities.
- Medical problems, including crush syndrome, compartment syndrome, exacerbation of respiratory illness, and hypothermia, will be encountered in US&R.

Chapter 193

Disaster Preparedness

Carl H. Schultz and Kristi L. Koenig

PERSPECTIVE

Disasters occur in all areas of the world and cause harm to people, property, infrastructures, economies, and the environment. Harm to people includes death, injury, disease, malnutrition, and psychological stress. Recent catastrophes include earthquakes in Pakistan (2005) and Haiti (2010) (Fig. 193-1); devastating tsunamis in the Indian Ocean (2004) and Japan (2011); massive hurricanes in the southern United States (2005); severe flooding in Australia (2011); tornadoes in Arkansas, Tennessee, and Kentucky (2008); and unusual weather conditions producing record snowfalls in the United States and Europe (2011). Increasing population density in floodplains and in earthquake- and hurricane-prone areas and the effects of global warming point to the probability of future catastrophic disasters with large numbers of casualties.

Factors that indicate an increasing probability of mass casualty incidents include terrorist activity; increasing population density in floodplains, seismic zones, and areas susceptible to hurricanes; production and transportation of thousands of toxic and hazardous materials; risks associated with fixed-site nuclear and chemical facilities (illustrated by damage to the Fukushima nuclear power plants after the 2011 Japan earthquake and tsunami); the possibility of catastrophic fires and explosions; and global warming. As an example, the U.S. Geological Survey has identified volcanoes in the western United States and Alaska that are likely to erupt in the future, including Mt. Hood, Mt. Shasta, and the volcano underlying Mammoth Lakes in California. Because of the rising population density in these areas, hazards from volcanic activity are increasing. Ash from the 2010 Eyjafjallajökull eruption in Iceland grounded aircraft in Europe for weeks.

Given this probability and the increasing role of emergency medicine in disaster preparation, mitigation, response, and recovery, this chapter discusses disaster planning and operations with emphasis on the role of the emergency physician. The emergency physician has extensive responsibilities for community disaster preparedness and disaster medical services, including response to terrorism. In position and policy documents, the American College of Emergency Physicians outlines the scope of emergency medicine's involvement in preparedness and response to disasters and terrorism, stating that "emergency physicians should assume a primary role in the medical aspects of disaster planning, management, and patient care" and that "emergency department personnel will become the *first responders* to a covert biological attack."[1,2]

A committed emergency department alone is insufficient to provide hospitals with a successful disaster preparedness program. Institutional commitment by every hospital department and the administration is necessary to coordinate effectively with system-wide resources for disaster management. This is especially critical for creation of hospital surge capacity.[3-5] A partial listing of general disaster medicine resources can be found in Table 193-1.

Surge Capacity

The concept of surge capacity has emerged as a way to manage an event that produces a sudden influx of casualties with medical and health needs that exceed current hospital resources.[6] This can be due to either the volume or types of victims. The three basic components of the surge capacity system are commonly referred to as the three *s*'s of staff (hospital personnel), stuff (supplies and pharmaceuticals), and structure (physical location and management infrastructure). A complete discussion of surge capacity is beyond the scope of this chapter but has been published elsewhere.[7]

Within the context of surge capacity, new protocols are being developed that address allocation of resources when the medical and health needs of a population exceed current inventory. The issues involve creation of an equitable system for scarce resource allocation strategies, including assignment to an intensive care unit. Although no universally accepted approach currently exits, a system to optimize patient outcomes in a resource-constrained environment is clearly needed.

NATURE OF DISASTERS

Definitions

One of the challenges facing those responsible for disaster preparation is that no standard definition of *disaster* exists. Some events that have been routinely classified as disasters clearly are not. For example, many would consider a plane crash a disaster, yet it may not even approach overwhelming of the resources of the local responders. Because disaster medicine is multidisciplinary and depends on the integration of multiple levels of responders, the use of a common, precise terminology is essential.

In general terms, an event can be considered a disaster when it overwhelms response capabilities. These response capabilities can change in diverse environments or even in the same location at different times of the day or days of the week. For example, a multiple-vehicle collision with 6 critically injured patients and 12 patients with minor injuries could overwhelm both the emergency medical services system and the hospital in a small rural community. In an urban area with multiple hospitals that participate in a trauma system, however, this same event could be managed with routine resources. Thus it is the functional impact on the specific entity that is the key concept in determining whether a disaster exists.

Classic Terminology

The words *internal* and *external* refer to a hospital setting to help distinguish whether an event has occurred within the hospital grounds (internal) or in the community (external). This concept distinguishes between preparing for casualties to arrive at the hospital and dealing with casualties or resource problems within the hospital. This geographic distinction between internal and external may be useful, but it has severe limitations. Many events can be both internal and external to the facility at the same time (e.g., major earthquake or hurricane). Furthermore, simply identifying the location of the event does not answer the critical question: How are response capabilities affected?

An etiologic descriptor for an event is another customary classification. It does not matter whether a disruption in the ability of the hospital to respond is caused by nature or by humankind. The key consideration is what actions are required to mitigate and then to rectify the situation. Although the terms *natural* and *man-made* are prevalent disaster descriptors, they generally do not add anything of value, and therefore some experts have advocated removing them from the disaster lexicon, particularly because the etiology of the event may be unclear in its initial aftermath.

Some definitions have been based on the number of casualties. As previously described, the absolute number of patients is much less important than whether their medical and health needs exceed the resources to care for them at a given point in time. Another historical scheme divides disasters into three levels. Level I denotes a situation in which local resources are adequate to care for casualties. For example, the 2002 collision between a freight train and commuter train in Orange County, California, was managed effectively by local responders. Level II means that regional mutual aid is required to respond to the event. This was the case at the Hyatt Regency Hotel in Kansas City in 1981 when two skywalks collapsed, killing 114 people and injuring hundreds. Level III incidents require state and federal aid. The attack on the World Trade Center in 2001 (Fig. 193-2) and hurricane Katrina in 2005 were such events, causing such massive destruction that federal disaster medical assistance teams were deployed to New York and Louisiana, respectively, to provide medical personnel and supplies.

Figure 193-2. The World Trade Center attack of 2001 overwhelmed local resources and necessitated state and federal help.

One model eliminates the word *disaster* and replaces it with the acronym for potential injury-creating event, *PICE*.[8-10] The PICE nomenclature is an attempt to resolve the issue regarding diverse meanings for *disaster*. This model is referenced in the Joint Commission standards and in publications from several countries. The PICE system is discussed here to help clarify important concepts in describing an event.

Potential Injury-Creating Event Nomenclature

The acronym PICE and its modifiers concisely describe the critical features of most types or degrees of disaster.[8-10] The same occurrence can have different effects at different points in time; thus, as an event evolves over time, its description may change.

Modifiers are chosen from a standardized group of prefixes along with a stage to indicate the need for outside medical assistance (Table 193-2). The first prefix (column A) describes the potential for additional casualties. The second prefix (column B) describes whether local resources are overwhelmed and, if so, whether they must simply be augmented (disruptive) or whether they must first be totally reconstituted (paralytic). The third prefix (column C) shows the extent of geographic involvement.[8-10] Column C refers strictly to the affected region and not to the

location that sends assistance. Rather, the “stage” rating scale defines the likelihood that outside medical assistance will be needed either to augment or to completely reconstitute resources.[8] Stage 0 means that there is little or no chance. Stage I means that there is a small chance and requires placing outside medical help on alert. Stage II means that there is a moderate chance and outside help should be placed on standby. Stage III means local resources are clearly overwhelmed and require the dispatch of outside resources and commitment of personnel. For example, a multivehicle collision with a dozen injuries and several deaths in a large city would be a stage 0, whereas in a small rural town it might be a stage III (Table 193-3).

A PICE can be either static or dynamic. *Dynamic* implies an evolving situation in which it is too soon after the incident to determine the numbers and types of casualties and the impact on the hospital. Alternatively, a *static* situation results if 10 people are injured in an incident and little potential for further harm exists.[8-10]

In some situations, enhancement of routine operations is not sufficient or possible. A PICE can completely overwhelm the capability to mount a normal response so that a substitute plan for recovery must be used. Situations that require significant reconstitution of critical resources are termed *paralytic*.[8-10] Within the hospital, there are six critical elements necessary to provide a response (Box 193-1).[11] If one or more of these resources are compromised, they must be reconstituted or a substitute must be implemented. Such paralytic events can be either destructive or nondestructive (Box 193-2).[8]

Hazard Vulnerability Analysis

An important consideration in disaster planning is an awareness of the types of events for which the hospital or community is vulnerable. The classic example is the monumental risk from earthquakes in the central United States resulting from the combination of the New Madrid fault and the limited seismic safety requirements for buildings in that area. The planner must learn what types of support are available from outside agencies (e.g., hazardous materials decontamination from fire departments and information from poison control centers). Although awareness of such resources is critical, contingency plans must be available when such assistance is not accessible.

After performing a hazard vulnerability analysis (www.emsa.ca.gov/disaster/files/kaiser_model.xls), emergency planners should consider the most probable events and prepare for them. There should also be planning for events that are rare but catastrophic.[12] The major peacetime threat to life and limb in the United States is probably a large earthquake in a densely populated area or a terrorist attack. The disaster planner should proactively identify all such hazards and prepare contingency plans for each.

TRIAGE

The term *triage* derives from the French verb *trier,* meaning “to sort.” The concept of triage was used as far back as Napoleon’s time to assign priorities to treatment of the injured when resources were limited. Priority is given to the most salvageable patients with the most urgent conditions. The emergency department uses triage in the hospital setting on a daily basis, but the focus of such triage is changed under disaster conditions.[13,14] Standard emergency department triage is intended to identify the most seriously ill patients first and to ensure that they receive rapid care. The goal of disaster triage is slightly different, that is, “to do the most good for the most people.” In other words, there is a shift from focus on individual patients to focus on the entire affected population.[15] It can be difficult for physicians to realize that to achieve the goal of maximizing benefit to an entire population of patients, they may need to let some patients die with only comfort care. Under true disaster conditions, cardiopulmonary resuscitation should not be performed.[16]

Routine Multiple-Casualty Triage

To assist in understanding of triage techniques, it is useful to consider a routine out-of-hospital event with multiple casualties

www.ketabpezeshki.com 66485457-66963820

(e.g., a multivehicle collision). In such situations, rescue personnel often use a Simple Triage and Rapid Treatment (START) technique that depends on a quick assessment of respiration, perfusion, and mental status.[17] These three assessments can be remembered by the mnemonic RPM (respirations, perfusion, and mental status). Initially, all victims who are able to walk are asked to move away from the immediate incident area. These patients are classified as green, or "walking wounded," and are reassessed after the more immediately critical patients are triaged.

The Pediatric Triage Tape (PTT) and JumpSTART have been proposed for the triage of children. JumpSTART is a modification of the START triage protocol that includes an additional step of five rescue ventilations for children presenting apneic and modification of criteria for hypoventilation and tachypnea as well as for a decrease in mental status. The PTT uses criteria that change in proportion to increasing victim size. The parameters for a child 50 to 80 cm in length are illustrated in Figure 193-3. In a comparison of sensitivity and specificity between the PTT and JumpSTART in pediatric trauma patients, the PTT demonstrated superior outcomes.[18] Both START and the PTT appear to be useful tools, but only START has been evaluated in an actual disaster situation.[19-21]

As illustrated in Figure 193-4, a rescuer can assess each patient in seconds, quickly checking respiratory rate, pulse, and ability to follow commands (mental status), and divide the patients into the remaining three categories: red (immediate), yellow (delayed), and black (deceased). The only patient care interventions provided during this process are the opening of an obstructed airway and direct pressure on obvious external hemorrhage. At this point, patients are generally transported to a hospital for definitive care. Most often, patients arrive with a color-coded triage tag and are reassessed and retriaged by the hospital staff (Fig. 193-5). An outcomes-based evaluation of the performance of START triage in an actual disaster (2002 Placentia Linda train crash) demonstrated acceptable levels of undertriage (100% sensitivity

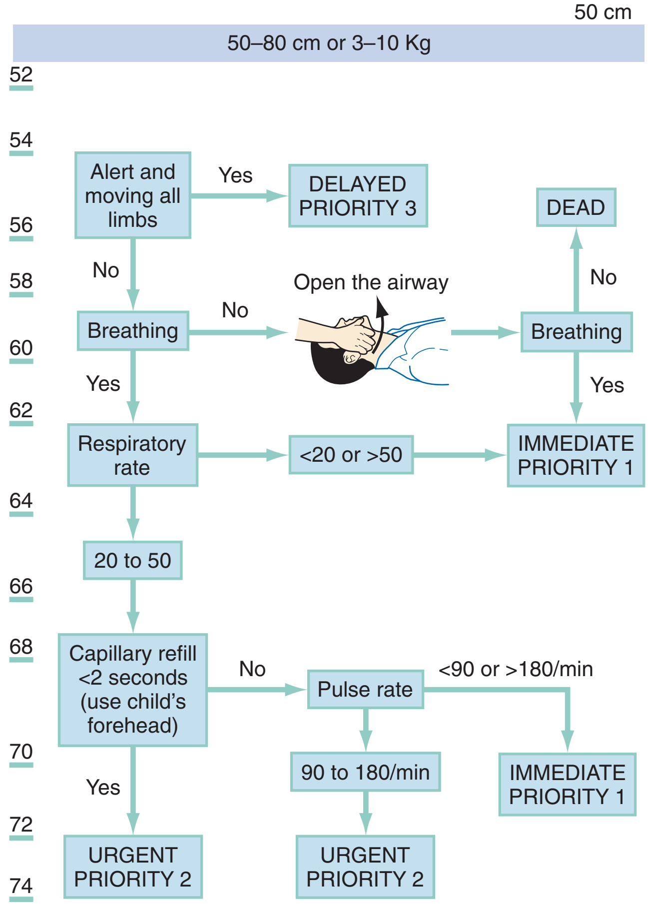

Figure 193-3. Pediatric Triage Tape algorithm for a child 50 to 80 cm in length.

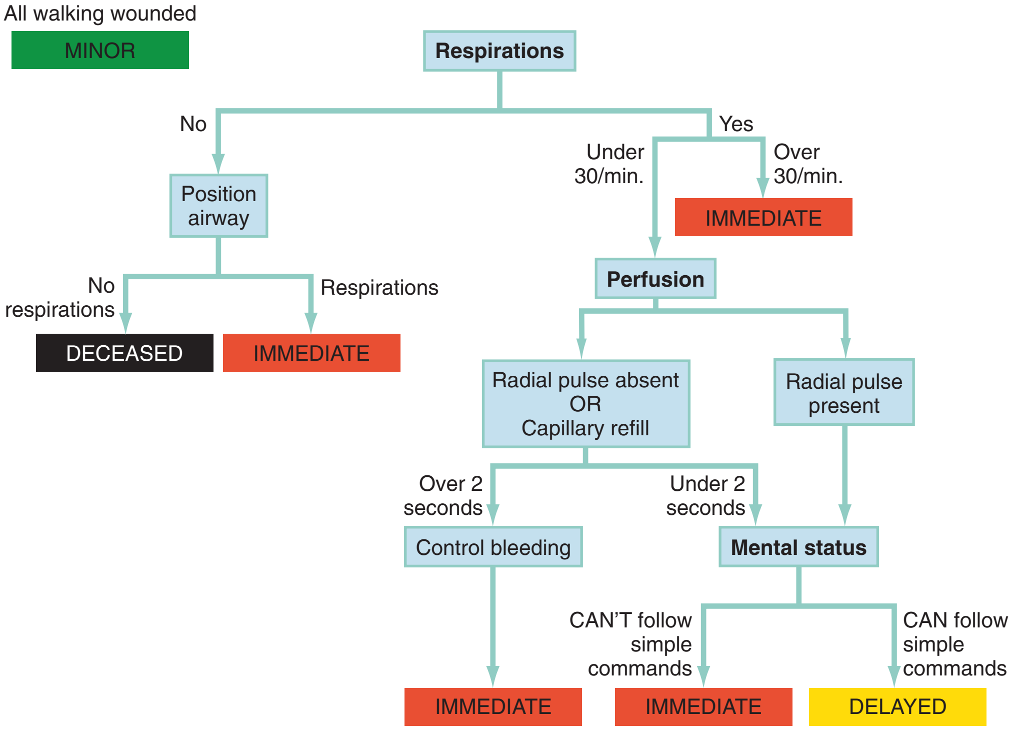

Figure 193-4. Simple Triage and Rapid Treatment (START). Victims who can walk are identified first and triaged into the "minor" category. Those remaining are triaged by the algorithm. (Modified from Triage—START and SAVE. In: Medical Disaster Response Training Course Syllabus. Dana Point, Calif, Medical Disaster Response, 1993.)

www.ketabpezeshki.com 66485457-66963820

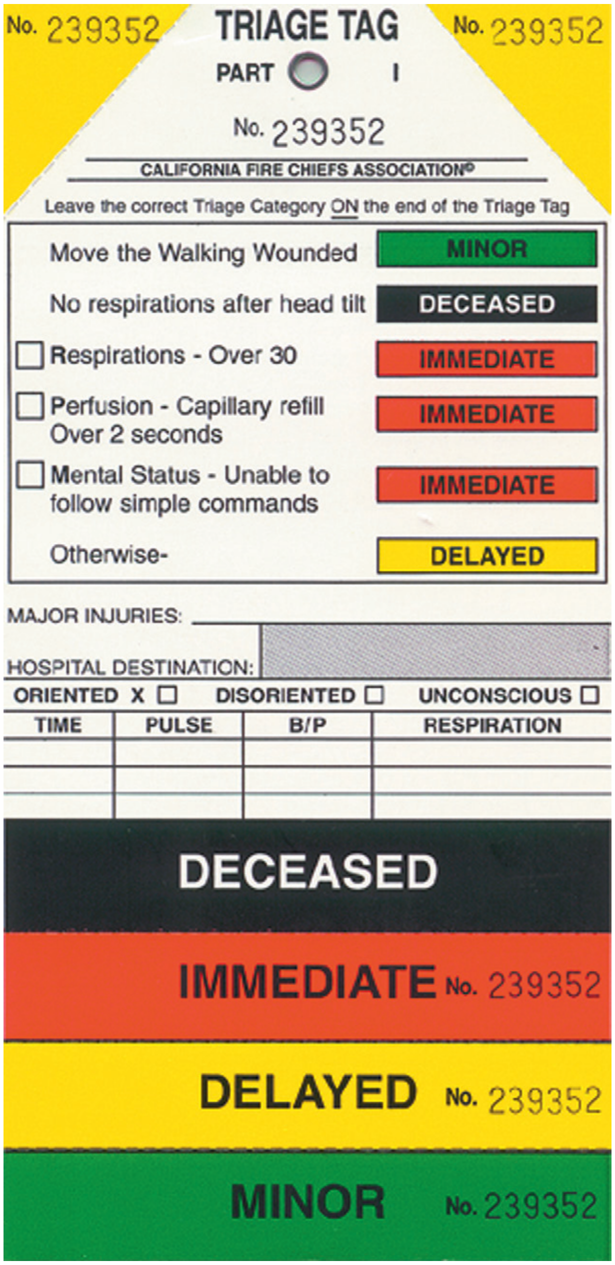

Figure 193-5. Triage tag to be used in multicasualty or disaster patient assessments.

of the red category and 90% specificity of the green category).[21] However, significant amounts of overtriage occurred. Use of START also appropriately prioritized the transport of victims, with patients triaged as red arriving at hospitals earlier than patients triaged as yellow or green.

Recently, a multidisciplinary group was formed to propose a potential national triage system for the United States. The result, derived by consensus of opinions, was referred to as SALT (sort, assess, lifesaving interventions, and treatment or transport).[22] It differs from START mainly in the assessment of respirations (relies on a qualitative evaluation of respiratory distress rather than a number), the requirement for performance of certain emergent interventions (chest decompression), and an unstructured estimate of survivability. The algorithm is more complicated than START, and no current data exist evaluating its sensitivity, specificity, or other performance characteristics in a disaster. As such, it is not currently possible to make recommendations for its use.

Catastrophic Casualty Management

Triage during a widespread, catastrophic disaster differs from triage performed in routine out-of-hospital and hospital settings. The number of victims is vastly increased, and medical resources are severely limited or even initially absent. Patients may remain on scene for an extended period and should be frequently reassessed. If hospitals remain accessible, patients tend to seek care at the closest one, a phenomenon known as convergence. Hospitals close to the disaster scene are overwhelmed, whereas hospitals located only a few miles away may receive few if any patients. More likely, the hospitals will be rendered nonfunctional. The triage process will then be decentralized, occurring at multiple sites, or compartments, simultaneously throughout the disaster zone. Rather than a single scene or localized disaster, this can be thought of as a compartmentalized disaster.

To address this situation, researchers developed the Secondary Assessment of Victim Endpoint (SAVE) system of triage.[23] The SAVE triage system is designed to identify patients who are most likely to benefit from care available under austere field conditions in a resource-poor environment. When it is combined with the START protocol, SAVE triage is useful for any scenario in which multiple patients experience a prolonged delay in accessing definitive care.

The SAVE methodology is designed for use by health care providers under two conditions: (1) for those working within the disaster zone that begin caring for patients immediately but may not be able to transport patients to a definitive care facility for days and (2) for those caring for patients within hospitals where demand for resources exceeds supply. This second situation can occur as hospitals attempt to increase surge capacity. It is immediate and dynamic rather than delayed and static. Although there are many elements in common with other triage systems, rapid transport to a functional medical center within the "golden hour" may not be possible.

The SAVE triage methodology divides patients into three categories: (1) those who will die regardless of how much care they receive, (2) those who will survive whether or not they receive care, and (3) those who will benefit significantly from austere field interventions. Only those patients expected to improve receive care beyond basic and comfort measures. With use of SAVE, patients are separated into these three categories so resources can be focused appropriately. The decision to place patients in a particular group is based on field outcome expectations derived from existing survival and morbidity statistics.[23] An example is a situation in which three victims require chest tubes (two victims require one tube each and one victim requires two tubes), but only two chest tubes are available. The SAVE principles guide providers to place their last two chest tubes into the two victims who need it rather than into the single victim requiring two tubes.

During the triage process, individuals who would most benefit from early transport should be marked as "first out," in case an evacuation opportunity occurs. These would be victims with medical problems readily treatable at a hospital or facility with equivalent capabilities but untreatable and fatal in the field. A patient requiring surgery for intra-abdominal hemorrhage is a common example.

Since nuclear, biologic, and chemical terrorism has become a threat, new triage systems are under development.[13,24] These systems attempt to incorporate the added threats from exposure and contamination into the triage process. One such method for biologic casualties triages many individuals to home observation rather than hospitalization to optimize resource use and to minimize the spread of the infectious agent.[24] In addition, responders must be protected from secondary contamination or exposure; therefore, part of the triage algorithm should include a risk assessment and determination of whether and what type of personal

www.ketabpezeshki.com 66485457-66963820

protective equipment should be donned before patients are assessed. A quick determination is critical to prevent patient deaths from traumatic injuries while awaiting medical care from responders concerned about their own health and safety. This is particularly true in a "combined event" scenario, such as an event involving a radiologic dispersion device. Also associated with terrorism incidents are large numbers of *psychogenic casualties,* those who believe they were exposed but actually were not and those at risk for post-traumatic stress disorder. The emergency plan should include a mechanism to assess and to sort these individuals so as not to overwhelm the emergency department and also provide mental health care. While performing triage, the emergency physician should also consider the effects of extremes of age, underlying disease, and multiple injuries when assessing the potential prognosis for a given patient. Fortunately, the treatment of many nontraumatic emergencies can be accomplished with field interventions that do not consume extensive resources. Therefore, patients with such illnesses should usually be triaged to the treatment area.

Vulnerable Triage Populations

Certain groups of patients, such as children, the elderly, and disabled persons, may have special needs that present challenges to routine triage. For example, if a person is too young to follow commands or is deaf, the individual would not be able to respond to a command to walk away from an incident site for reasons that may not indicate severe injury. Triage schemes should accommodate language and cultural barriers as well as physical and psychological limitations that result in social or medical vulnerabilities.

Special Triage Categories

To maximize personnel resources, disaster victims who would normally be triaged to the observation area can be triaged to the treatment area if they possess special skills valuable to the medical team (e.g., medical expertise and translation skills). By the increase in the number of functional team members, the effectiveness of the overall response will improve. The guiding principle supports the disaster triage goal of maximizing benefit to the most people.

CARE OF SPECIAL NEEDS POPULATIONS

Within the general population, groups of unique individuals exist that are at greater risk for injury, death, and property loss resulting from a disaster. These vulnerable populations include children, the elderly, racial and ethnic minorities, the disabled, those residing in institutions such as skilled nursing facilities, and the mentally ill. Challenges in the management of these populations with special needs during a disaster include lack of mobility, tracking of victim movement during evacuations and issues of reunification with responsible family members, inability to understand English or to comprehend instructions issued by local authorities, and poor access to transportation resources. A detailed discussion on the disaster management of these populations is beyond the scope of this chapter but available elsewhere.[25,26] Those responsible for disaster planning should ensure that policies and procedure are developed that address the unique needs of such groups.

OUT-OF-HOSPITAL RESPONSE

Emergency Medical Services System Protocols

To prepare adequately, hospitals must be familiar with and involved in the development of county or regional plans. For example, some emergency medical services systems use automatic systems such that each hospital may be expected to accept a fixed number of critically ill or injured and minor patients without previous notification.

Physicians working at hospitals should be familiar with community disaster management operations, including the function of the emergency operations center.[11] Mutual aid agreements with other hospitals or regions should be considered for situations in which current hospital capacity is exceeded or evacuation is necessary.

Incident Command System

Some form of an incident management system is now a standard component of emergency command and control throughout the United States. It provides a flexible management structure on which to organize a response.[27] The federal version, known as the National Incident Management System, is incorporated into the National Response Framework and provides strategic guidance on the U.S. government's involvement in disaster response. All states must use an incident management system, and it must be compliant with the National Incident Management System.[28] By standardizing an organizational structure and using common terminology, an incident command system provides a management configuration that is adaptable to events involving a multiagency or multijurisdictional response. At the most basic level, there are five functional elements in the organizational structure: incident command, operations, planning, logistics, and finance. The principles of an incident command system can also be applied to the hospital setting through implementation of a Hospital Incident Command System. With this type of organizational infrastructure and the flexibility to expand and to collapse functions as needed, an orderly and efficient response to any incident can be accomplished. Because hospitals cannot anticipate every contingency, a system such as the Hospital Incident Command System assists with planned improvisation. The Joint Commission (formerly known as the Joint Commission on Accreditation of Healthcare Organizations) standards require use of an incident management system in health care facilities.

Incident Command

The incident commander has overall management responsibility for the incident. Physicians should understand that they are not in charge at the scene of an out-of-hospital incident.[28] In general, nonhospital providers can manage the scene, and physicians should remain at the hospital to provide definitive care. When a physician is on scene, the best way to assist is to ask the incident commander where medical help is most needed.

The incident commander may choose to appoint a command staff to manage public information, safety, and interagency liaisons.[27] When an event involves multiple jurisdictions, a unified command is established that coordinates a common and consistent action plan to make the best use of available resources.

Operations Section

The operations section has a chief who is responsible for the management of all incident tactical activities.[27] This section can be expanded and subdivided into branches (e.g., law, fire, and medical) and divisions. Operations also manages the resources assigned to staging areas. Ambulances, personnel, and supplies should be staged outside the perimeter of the scene and directed in as needed rather than converging on the disaster site, potentially disrupting activities and blocking the exodus of patients. It is under the operations section that all medical triage and care is provided.

www.ketabpezeshki.com 66485457-66963820

Planning Section

The planning section collects, evaluates, and disseminates information about incident operations and the status of resources. This section also develops incident action plans and conducts planning meetings.[27]

Logistics Section

The logistics section's chief is responsible for providing facilities, services, and material in support of the incident. This includes procuring equipment and supplies, providing food and medical support, and meeting transportation needs.[27]

Finance Section

The finance section is responsible for maintaining records on personnel and equipment, providing payments to vendors for supplies and use of equipment, and determining the cost of various alternatives for strategic planning.

Organization of the Out-of-Hospital Disaster Scene

The disaster site is organized into several distinct areas. The command post is the nerve center of the operation and contains the incident commander and section chiefs. A staging area for incoming personnel and equipment should be established on the outer perimeter. If air evacuation is needed, a safe landing zone must be identified. A casualty collection point and morgue should be designated. In conjunction with an incident command system, this structure brings order to the response.

PLANNING AND HOSPITAL RESPONSE

Comprehensive Emergency Management

The comprehensive emergency management all-hazard approach to disaster preparedness has been a Joint Commission requirement since January 2001. Comprehensive emergency management consists of four phases: mitigation, preparedness, response, and recovery.[29,30] *Mitigation* involves taking actions to reduce the impact of identified hazards. Training, drills, and cataloging of resources are examples of *preparedness* activities. *Response* includes assessment of the situation and coordination of resources. Finally, *recovery* consists of a return to normal operations and debriefing to critique the response and to provide long-term psychological support to the victims and rescuers.

As required by the Joint Commission, a hospital's disaster or "emergency management" plan must address events that occur both inside (internal) and outside (external) the institution.[30] Because some incidents affect both internal and external operations, a hospital emergency management program should contain plans that address all circumstances.

Hospital Disaster Response Plan

A disaster event can disrupt daily, routine hospital functions. This can represent an infrastructure failure (e.g., loss of electric power and water) or a threat to the safety of patients and hospital personnel (e.g., labor dispute or approaching hurricane). Because the response varies from postponement of elective surgery to facility evacuation, every hospital department must participate in the planning process. At a minimum, the disaster plan should clearly delineate the circumstances in which the plan is activated; identify the command structure with defined lines of authority and responsibility; describe a response strategy for each anticipated incident; estimate an incident's impact on safety and hospital function, providing for evacuation if necessary; and list essential information, such as critical telephone numbers (e.g., elevators, key personnel, and pay telephones), community agencies (emergency medical services, police, and public health), and sources of vital supplies (water, oxygen, and drugs).[29]

After plan activation, the primary role of the emergency department is to assess and to treat individuals with illness or injury. In the absence of casualties, other hospital departments primarily manage disasters that disrupt hospital operations. Nevertheless, the medical director of the emergency department should continuously monitor the response process.

In the unlikely event that evacuation of the emergency department is necessary, evacuation routes and relocation destinations that have been planned in advance maximize safety and efficiency. When resources are plentiful, emergency department patients in critical condition are assigned the highest priority for evacuation and transport. Less ill patients receive a lower priority.[31] When resources are limited (e.g., in the event of a large-magnitude earthquake), the reverse strategy applies. The least critically ill patients receive the highest priority for evacuation.

Another scenario would be an event occurring in the community that results in a sudden influx of patients requiring emergency care at hospitals. This type of incident has no direct impact on hospital capacity or function. However, the need to rapidly increase surge capacity may require implementation of different patient management strategies (i.e., temporary creation of alternate care sites on hospital grounds). Participation in the planning and execution of the hospital disaster response is an important administrative responsibility.[16] Available data guiding development of disaster strategies are incomplete, but an effective disaster response can be created by reviewing the essential components of disaster plans and the previous experience of hospitals.[16,29,31,32] A member of the emergency department must have a leadership role in the planning and implementation of the disaster plans.

Basic Components of a Hospital Comprehensive Disaster Response Planning Process

Interdepartmental Planning Group

The interdepartmental planning group has the responsibility for hazard identification and disaster preparedness activities. The process of conducting a hazard vulnerability analysis is complex, but templates such as the one created by the Kaiser Foundation Health Plan may be informative.[33] Frequently referred to as the disaster or emergency preparedness committee, it is composed of representatives from all departments vital to the hospital's response, including administration, medical staff, nursing, safety, security, emergency department, and engineering. Additional input may occasionally be necessary from outside agencies (e.g., fire department, hospital suppliers of goods and services, and emergency medical services agency).

The committee should be structured to ensure that the plan is properly constructed, tested, and executed. Hospital resources must be provided to support the planning process and testing of the plan, and there must be a detailed educational program for all affected hospital staff.[30,34]

Resource Management

A full inventory of the hospital's resources is necessary. In addition to equipment, space, and personnel within the institution, potential support from outside the hospital must be sought. It is also necessary to develop contingency plans to compensate

www.ketabpezeshki.com 66485457-66963820

for lost resources (e.g., failure of hospital computers during a power outage or cyber attack). Augmentation of such resources is critical to the successful increase of the hospital's surge capacity.[4,5,35]

Strong relationships with community agencies (e.g., fire department and regional emergency medical services system) are important to ensure a coordinated disaster response. Hospitals located near companies using large amounts of hazardous materials are required by Title III of the Superfund Amendments and Reauthorization Act to participate in local emergency planning committees, sometimes termed LEPCs.[36]

Command Structure

An organized system establishing lines of authority and decision responsibility must be in place. This system should designate a command center where the disaster response can be coordinated and create a clear chain of command. This prevents confusion if certain individuals are missing, a common situation on nights and weekends or in cases of a community-wide disaster during which hospital personnel may become victims. The command center should contain sufficient equipment to support command and control functions, even if the center must be moved as a result of hospital damage. Implementation of the Hospital Incident Command System or similar management structure will support all such requirements.

Media

The media can be an important source of information but can also significantly disrupt the hospital's disaster response. Therefore, arrangements should be made in advance for a designated individual to coordinate all media interactions and for these briefings to occur in a designated location. Media coordinators should inform reporters of the time they will receive their next update so they do not intrude on response operations while trying to obtain information. A strong media liaison can facilitate dissemination of important information to the public, such as that no blood shortage exists so that individuals refrain from coming to the hospital to donate blood. In fact, crisis and emergency health risk communication is now an important part of managing the disaster response and can have a significant impact on the public's perception of events.[37] Individuals designated the media coordinator should be familiar with the basic principles of emergency health risk communication. Security should be involved in managing the media response to the hospital and in preventing media from interfering with triage and treatment of patients.

Communication

Communication systems are probably the most important but also most vulnerable component of a disaster plan.[16,31] Redundant systems are essential. Those responsible for mobilizing the emergency response require access to at least one other communication system besides the telephone (which is frequently one of the first systems compromised during a disaster). Two-way radios are often used, as are pay telephones, independent fax lines, and cellular phones. Another option is the use of satellite phones and wireless hand-held devices to transmit e-mail messages. Recent advances in communication technology exemplified by Facebook and Twitter show promise. Survivors of the 2011 Japan earthquake used these techniques to provide early information to the outside world on conditions within the disaster zone.[38] Runners are also useful for intrahospital communication if all else fails.

Personnel

The disaster plan must include a roster of all critical positions and personnel and establish a reliable method for their mobilization. Several individuals should be assigned to each position in case some personnel cannot be reached. A protocol for managing volunteers is also crucial. A large group of uncontrolled volunteers descending on a hospital ("convergent volunteerism") can be as disruptive as the disaster.[39]

Credentialing of volunteer health professionals in a timely manner so hospitals can use their services during a disaster remains a challenge. A federally supported program known as the Emergency System for Advance Registration of Volunteer Health Professionals (ESAR-VHP) is attempting to address this problem. It will provide a system for credentialing of volunteer health care providers in advance of a disaster so they will have emergency privileges should the need for their services arise.[40] There remain significant challenges with such a system, including whether sufficient numbers of providers will participate, how fast they can deploy, how well qualified they will be, and whether they will have competing obligations during a disaster. An alternative system that permits hospitals to recognize each other's credentialing process through a shared database shows promise. Not only will this alternative system facilitate participation by most health care providers, but it also permits hospitals to grant emergency privileges within minutes after a disaster.[40]

Patient Management

A systematic approach to patient management is necessary to maximize resources. This includes protocols for decontamination, triage, patient prioritization, evacuation, and control of patients' families. Alternative use of hospital facilities should be anticipated, such as the conversion of a parking lot into a clinic area for suturing of lacerations or a decontamination zone. Provisions for patient identification and treatment documentation are also important to facilitate federal and third-party reimbursement at the conclusion of the disaster.

Training Exercises

Disaster exercises are one of the more effective ways of familiarizing hospital staff with their responsibilities. All hospital departments should participate, and community agencies should be involved. The Joint Commission requires two drills a year; these should mimic incidents that are likely to occur. Methods to assess the effectiveness of these exercises as measures of overall hospital disaster preparedness are improving.[41]

REVIEW OF HOSPITAL AND COMMUNITY DISASTER RESPONSE EXPERIENCE

Disaster plan implementation is complex and difficult. Knowledge can be gained from review of previous disaster response experiences, resulting in improved implementation strategies. The following discussion highlights potential challenges.

Focal Disasters

Most disasters experienced by hospitals are focal in nature. Hospital function is typically unimpaired. The majority of problems encountered are related to a sudden increase in patient volume and acuity or arrival of patients with illnesses not usually treated at that facility (e.g., burns, radiation exposure, and severe acute respiratory syndrome).

www.ketabpezeshki.com 66485457-66963820

Hospitals frequently experience difficulty in effectively using and interfacing with community resources. Field triage should allocate patients rationally, and transfer agreements must be in place to facilitate interhospital movement of patients and evacuation of patients to alternate care sites.

Media access must be controlled. During the Loma Prieta earthquake in 1989, a news helicopter occupied a nearby community hospital's only landing zone, preventing the possibility of landing a medical helicopter.

Redundant communication systems must be in place. Typical backup systems to the telephone are radios and cellular phones, but the frequencies can be overloaded in both systems. Use of cellular phones for text communication may offer another solution. Two-way radios are reliable and should be part of the communications network. Satellite phones are also an option.

Catastrophic Disasters

In a large-scale disaster, paramedics may be unavailable to assist in patient transfers or hospital evacuations. Disaster medical assistance teams and urban search and rescue teams will deploy, but their time to arrival on scene may be variable. Each individual hospital may have to remain self-sufficient for 48 to 72 hours or longer.[42] Generator problems are frequent; they either fail altogether (as they did during the Loma Prieta earthquake) or supply insufficient power to meet emergency needs (as during the Northridge earthquake). Evacuation plans must not require elevators for this reason. Telephone service will cease as lines are disrupted or deliberately restricted by the phone company. Cellular phones may function within a local area, but failure is likely if more distant sites within the city are dialed. Hospital radios designated for disaster use should have the hardware secured to prevent earthquake damage.

Under catastrophic conditions, mobilization of personnel is more difficult. Because telephone communication is unreliable, at least one additional system to contact personnel at home should be in place. An alternative is to institute an automatic response system, in which personnel report to the hospital or another location when communications are impaired.

After earthquakes or explosions, immediate access to structural engineers is important. In the Northridge earthquake, eight hospitals in the Los Angeles area sustained enough damage to force evacuation of at least one patient. Four institutions completely evacuated their facilities in the first 24 hours, including two hospitals that met the most current structural earthquake standards. Further structural damage was subsequently identified, and two additional hospitals were forced to evacuate completely in the next 2 weeks. Ultimately, four of these hospitals were permanently closed and demolished.[31]

Hospitals are also vulnerable to hurricanes. In a study of hurricane Rita's (2005) impact on regional hospitals in Texas and Louisiana, seven hospitals were forced to evacuate patients.[32] Significant problems included prolonged loss of power, potable water, and staff. It was also difficult to obtain vehicles for transportation of patients to other facilities. Nonmedical vehicles were sometimes used to evacuate stable patients.

Catastrophic earthquakes can cause extensive casualties, including large numbers of patients with crush syndrome and lacerations. Up to 90% of victims with serious but survivable injuries are rescued by local responders and volunteer citizens in the first 24 to 48 hours. Therefore, special medical teams, such as disaster medical assistance teams and urban search and rescue teams, may not significantly affect survival from acute injuries if they arrive after more than 48 to 72 hours. If hospitals are not functional and no backup plan exists, immediate advanced medical care will not be available, and many people will die. Therefore, planners should include a backup system to provide medical care at alternate non-hospital care sites.

Need for Local Response

Currently, it is not possible for outside assistance to arrive in force during the crucial first 48 hours after the event. Therefore, an alternative source of immediate, sophisticated medical care is necessary. It appears this is best provided by local responders who can begin caring for patients soon after the event.[43] The Medical Disaster Response Project is the most advanced model of a local medical response to such a disaster. Developed by emergency physicians in southern California, the Medical Disaster Response Project has two components: (1) training of health care providers in the management of disaster victims under austere conditions and (2) placement of sophisticated medical supplies at designated sites within the community.[42] Under this plan, victims could receive rapid, advanced medical care from surviving volunteer health care providers even if hospitals were destroyed. The current Strategic National Stockpile is modeled after components of this plan. In addition, it was used as a major source document for the development of the Medical Reserve Corps.

Toxic Disasters (Hazardous Material)

Hospitals in the vicinity of major chemical industries, transportation corridors, or probable terrorist targets (e.g., major theme parks or nationally symbolic buildings) should be aware of potential hazards from incidents involving chemical and radioactive substances and be prepared to decontaminate large numbers of individuals exposed to these hazardous substances. Effective decontamination of victims and the need for safety measures on the part of rescue personnel to prevent secondary contamination are critical.[44] Decontamination equipment should be stored near the emergency department, and the staff must be trained in its use. This location must be known to personnel.[45] When such an emergency occurs, there is little time to search the hospital for the necessary supplies.

Ideally, patients contaminated with hazardous chemicals should first be brought to a designated decontamination area containing a warm-water shower with a container to hold drainage water. Victims should remove all clothing. Clothing and valuables are bagged, tagged, and stored. Contaminated patients must never be brought into regular patient care areas because of the danger of contaminating other patients, hospital staff, and equipment. In 1994, paramedics unsuspectingly transported a patient contaminated with a degradation product of dimethyl sulfoxide to an emergency department in Riverside, California. Before the presence of the hazardous material was detected, six health care workers were exposed, including an emergency physician. The emergency physician experienced a near-fatal exposure and required intubation and an extensive stay in the hospital's intensive care unit. Uncontrolled spread of the toxin resulted in evacuation and temporary closure of the emergency department.[46]

The emergency department must close off the air intake vents in rooms containing contaminated patients so toxic products do not enter the ventilation system and circulate to other areas of the hospital. Rescue personnel and hospital staff should be protected by gowns, gloves, and masks and, if necessary, supplied air respirators. The goals are to reduce the initial level of external contamination, to contain the contamination that remains, and to prevent further spread of these potentially dangerous substances to other patients and staff members (secondary contamination).

www.ketabpezeshki.com 66485457-66963820

CHEMICAL, BIOLOGIC, RADIOLOGIC, NUCLEAR, AND EXPLOSIVE TERRORISM

In addition to the familiar threat from hazardous materials, there is another challenge: a potential attack by terrorists using biologic, radiologic, or chemical weapons (see Chapter 194). Although somewhat similar to hazardous materials situations, management of patients exposed to weapons of mass destruction (WMD) requires additional knowledge and skills. Expertise in the management of patients attacked with unconventional weapons is important, but emergency physicians should also be familiar with treatment of blast injuries. High-explosive events, including suicide bombers, remain the most probable type of terrorism.

The most likely radiation source used by terrorists will probably not come from the detonation of a nuclear weapon. Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are believed to be the source of choice. They do not explode and give no warning of their presence. Terrorists can also dismantle such devices and incorporate the radioactive source into an explosive radiologic dispersion device ("dirty bomb"). Therefore, providers must recognize the presentation of patients suffering from radiation exposure to make the diagnosis. In addition to damage from radiation, these casualties may also suffer blast injuries. Initial treatment of such victims, if they are critically injured, should address stabilization of the blast injuries first before the radiation exposure is considered. Patients who are irradiated but not externally or internally contaminated pose no threat to emergency department personnel.

One of the greatest challenges with respect to WMD is the detection of biologic weapons. Patients exposed to biologic agents often initially present with vague symptoms associated with influenza-like illnesses. Decontamination is not a priority unless the exposure is immediate; standard precautions are generally sufficient.

Unlike radiologic or biologic weapons, chemical agents produce symptoms quickly. The challenge is decontamination and treatment. Approximately 80% of mass casualty decontaminations are performed at hospitals. Therefore, hospitals must be prepared to decontaminate patients outside the emergency department. Personal protective equipment is also essential for responders and hospital "first receivers" because of the risk of exposure during the decontamination process.[45,46]

DISASTER STRESS MANAGEMENT

Emergency health care providers experience high levels of stress when responding to the needs of disaster victims. If this excessive stress exceeds the capacity of normal coping mechanisms, it can potentially interfere with job performance and produce symptoms, including depression, sleep disturbances, increased use of alcohol and drugs, irritability, and anxiety. Post-traumatic stress disorder can result. In an attempt to reduce the psychological impact of these events on medical responders, various therapeutic techniques have been introduced throughout the years and are collectively known as critical incident stress management. This formal process of resolving emotional conflict using mental health professionals is now widely practiced.

In general, the longer the delay between exposure to the critical incident and subsequent psychological intervention, the smaller is the chance for a successful outcome. Therefore, the critical incident stress management process is designed for rapid implementation. During the incident, stress management staff or even a colleague can provide on-scene intervention. The goal is to assist the health care worker in regaining emotional control by facilitating communication of feelings and reactions through listening and support.

If a critical incident has profoundly affected participants and if symptoms are still present many hours later, urgent assistance is provided in the form of defusing. The critical incident defusing process is coordinated by mental health and peer support staff and focuses on information and venting of emotions. This process often takes place away from public view to protect confidentiality. If the psychological stress is severe, the process transitions to formal care provided by psychiatrists or psychologists.[47] Data from previous experiences suggest that such intervention can assist providers in maintaining job performance and satisfaction.

In addition to disaster health care providers, the victims themselves can suffer significant psychological trauma. Rapid identification of such individuals is a priority and can be facilitated by use of a recently developed psychological triage algorithm known as PsySTART. The tool itself has been previously validated and, in a recent trial, appears to assist health care workers in rapidly identifying patients who may benefit from acute psychological intervention.[48]

DISASTER MANAGEMENT AND RESPONSE ORGANIZATIONS WITHIN THE U.S. GOVERNMENT

Department of Homeland Security

The Department of Homeland Security (DHS), a cabinet-level department formed after the terrorist attacks of September 11, 2001, is the federal government's lead organization for emergency management activities in the United States. The Federal Emergency Management Agency (FEMA) was incorporated into DHS and retained its name. DHS has a coordinating responsibility for the entire spectrum of disasters irrespective of their size or etiology. DHS assists state and local organizations to mitigate, to prepare for, to respond to, and to recover from emergencies and is a source of funding for these endeavors. In 2003, the President directed that the DHS develop a National Incident Management System and a National Response Plan. Existing federal plans, including the National Response Plan, were then incorporated into the National Response Framework. The National Response Framework includes 15 Emergency Support Functions (ESFs.) Each has a primary (lead) federal agency and many supporting agencies. ESF #8 is entitled Public Health and Medical Services and is of key importance to the health care community. The primary agency is the Department of Health and Human Services (DHHS). Examples of functions within ESF #8 include coordination of health care personnel, supplies, pharmaceuticals, surveillance and reporting, and mass fatality management.

Urban Search and Rescue (ESF #9 of the National Response Framework)

When a building collapses because of an earthquake, terrorist bombing, structural failure, or other reason, various challenges confront rescue and medical personnel.[49] Some victims require field amputations to facilitate extrication,[49] and use of urban search and rescue teams and effective emergency medical care may improve the outcomes of such lifesaving efforts. This national system of multidisciplinary task forces is designed for rapid deployment to the sites of collapsed structures.[50] The medical team's responsibilities include caring for task force members, victims recovered by search and rescue activities, and the search team's dogs. There are also WMD urban search and rescue teams trained by FEMA to respond to nuclear, biologic, and chemical terrorist attacks.

www.ketabpezeshki.com 66485457-66963820

Department of Health and Human Services

On December 19, 2006, the President signed the Pandemic and All-Hazards Preparedness Act (S. 3678) into law and created a new position, the Assistant Secretary for Preparedness and Response (ASPR), within the DHHS. The office of the ASPR oversees the department's responsibilities for emergency preparedness and response activities, including the National Disaster Medical System (NDMS) and the Hospital Preparedness Cooperative Agreement Program, the coordination of the Medical Reserve Corps, the ESAR-VHP, the Strategic National Stockpile, and the Cities Readiness Initiative.

National Disaster Medical System

The NDMS is a federally coordinated initiative designed to augment the emergency medical response capability of the United States in the event of a catastrophic disaster. This system is a cooperative program of four agencies in the federal government: the Department of Defense, the DHHS, the DHS, and the Department of Veterans Affairs (VA). Although oversight of the NDMS has moved between federal departments, the DHHS currently has the lead for the NDMS. The NDMS provides an interstate medical mutual aid system linking the federal government, state and local agencies, and private sector institutions to address the medical needs of victims of catastrophic disasters. Its medical response element includes dozens of volunteer civilian disaster medical assistance teams that supplement the local medical infrastructure.

In a disaster, the NDMS is activated when state resources are overwhelmed and the governor makes a request for federal assistance. The disaster medical assistance teams must meet specific NDMS standards. Throughout the NDMS, emergency physicians are taking key roles in defining training standards, the deployment of clinical services, and the administration of field operations and in developing the concept of a civilian-federal disaster response capacity during national emergencies.

Centers for Disease Control and Prevention

The Centers for Disease Control and Prevention (CDC), based in Atlanta, is a U.S. federal agency under the DHHS. Its major responsibilities include preparing for and responding to public health emergencies (e.g., disasters) and conducting investigations into the health effects and medical consequences of these events. The major aims of CDC researchers are to assess the risks of death and injury and to develop strategies to prevent or to mitigate the impact of future disasters. Other responsibilities of CDC staff in the area of emergency preparedness and response include rapid assessment of the health and medical needs of disaster victims in the immediate postdisaster period; development and maintenance of national systems for acute environmental hazard surveillance; and provision of epidemiologic, sanitary, laboratory, and other relevant scientific support services to agencies involved in disaster planning and response.

Metropolitan Medical Response System

Metropolitan Medical Strike Teams (MMSTs) are highly trained, readily deployable, and fully equipped groups of medical, fire, and rescue professionals. As a component of the larger Metropolitan Medical Response System (MMRS), they support other local personnel in treating the victims of a chemical, biologic, or nuclear attack. In 2008 the MMRS expanded to include 124 participating jurisdictions. Although composed of local personnel, MMSTs are under the direction of the DHS. Their goal is to enhance local planning and response capability. However, hospital and community planners must still create an independent response because MMSTs require 90 minutes or longer to deploy.[51] MMSTs are equipped with chemical agent monitoring devices, protective equipment, and pharmaceutical supplies.

Department of Veterans Affairs

The VA has not traditionally been regarded as a disaster response entity. However, one of the VA's four legally mandated missions is emergency management. A unique feature of the VA is that its facilities and personnel are situated nationwide, and these are used to support federal health and medical assistance to state and local governments during disasters. The VA has highly trained specialty personnel who can support disaster medical activities. In addition to the vast pool of human resources, the VA provides large amounts of the pharmaceuticals and expendable supplies for on-site disaster support. For example, the VA purchases the contents of the CDC's Strategic National Stockpile. VA support is coordinated through the DHS and DHHS, as the lead federal agency for health and medical response. In addition to the VA's role in the federal response to disasters, as the largest integrated health care system in the nation, it has a well-developed hospital emergency management program. The VA *Emergency Management Program Guidebook* is an open-source reference that provides up-to-date information on emergency management concepts and various templates for emergency operations plans and hazard vulnerability assessment tools for hospitals.[52]

Department of Defense

On April 17, 2002, Secretary of Defense Donald Rumsfeld announced the formation of the Northern Command, or NorthCom, to assume responsibility over all military forces that operate within the United States in response to external threats and in support of civil authorities. The stated purpose of NorthCom is to assist the Department of Defense to better deal with natural disasters, attacks on U.S. soil, or other civil difficulties. It will provide for a more coordinated military support to civil authorities, such as the Federal Bureau of Investigation (FBI), FEMA, and state and local governments. Another important asset at the state level is the National Guard. The governor has authority to activate the National Guard for its disaster response and recovery missions.

FUTURE DIRECTIONS

The field of disaster medicine has become a major subspecialty within emergency medicine, and standing committees and membership sections for disaster medicine are now organized within the American College of Emergency Physicians and the Society for Academic Emergency Medicine. There are also numerous national and international forums for the presentation of disaster medical research results. Since the American College of Emergency Physicians first defined a disaster medicine curriculum suitable for residencies and fellowships, a number of disaster medicine fellowships have been established in the United States and elsewhere.[53] Disaster medicine textbooks and journals are increasing. In the 21st century, disaster medicine will continue to develop as a professional activity and unique academic specialty.

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- Comprehensive emergency management consists of four phases: mitigation, preparedness, response, and recovery.
- Mass casualty planning must account for the fact that traditional transport and communications systems will break down.
- Field personnel should be specifically trained in mass casualty triage and stabilization because austere field conditions change management strategies.
- All plans must protect caregivers and rescue personnel.
- Critical incident stress management may be highly desirable after an event and should be planned for in advance.
- Planners should establish and exercise a hospital-based incident management system.
- Disaster planning must include policies to address the needs of vulnerable populations, such as children, disabled, and the elderly.

Chapter 194

Weapons of Mass Destruction

Carl H. Schultz and Kristi L. Koenig

PERSPECTIVE

Besides managing the injuries and illnesses from common disasters such as earthquakes and airplane crashes, emergency physicians should also have competence in treating victims generated by terrorist attacks with nuclear, biologic, chemical, or high-energy explosive weapons. Conventional explosives remain the most common weapon used by terrorists; however, the risk from nuclear, biologic, and chemical agents may increase over time. The nomenclature for these weapons remains controversial. Some authors have proposed the use of *weapons of mass effect* or *weapons of mass disruption*. The military uses the acronym CBRNE, pronounced "see-burn-ee," referring to *c*hemical, *b*iologic, *r*adiologic, *n*uclear, and *e*xplosive. This chapter uses *weapons of mass destruction* (WMD) because of its wide acceptance.

The results of an attack with WMD, although admittedly of low probability, are potentially catastrophic. According to a World Health Organization estimate, 50 kg of anthrax spores aerosolized above a city of 5 million people would result in 100,000 deaths, with an additional 150,000 people seriously infected. The cost of managing 100,000 cases of anthrax exposure is estimated at between $6.4 and $26.2 billion.[1] Given these considerations, most authorities believe that preparedness for such threats is a priority.

Children are particularly vulnerable to these weapons. They breathe at a faster rate than adults do, increasing their relative exposure to aerosolized agents. Some chemicals, such as sarin, are heavier than air, so they tend to accumulate at the level where children are more likely to inhale them. Children have a greater surface area–to–volume ratio and their skin is thinner. This makes them more susceptible to agents that act on or through the skin. They have smaller fluid reserves and higher metabolic rates. Therefore, they are more vulnerable to dehydration from vomiting and diarrhea and suffer increased toxicity from a given exposure, such as to radioactive iodine (^{131}I).

The use of biologic and chemical agents dates to biblical times, although the threat from radiation and nuclear detonation is relatively new. Assyrians poisoned the wells of their enemies with rye ergot in the 6th century BC. The Mongols catapulted bodies infected with bubonic plague over the walls of Kaffa in the 14th century. The British Army gave American Indians blankets taken from individuals infected with smallpox during Pontiac's Rebellion in 1763. During World War I, the Germans effectively used chlorine and mustard agent against the advancing Allied armies. The Japanese killed hundreds to thousands of Chinese citizens with bubonic plague during World War II by spraying towns with fleas infected with *Yersinia pestis*. Saddam Hussein used a mustard agent against the Iranians during the Iran-Iraq War in the 1980s.

The use of WMD has been predominantly by the military during times of conflict. In recent history, however, the use of these agents has taken an ominous turn. Nonaffiliated groups have begun using WMD directed at civilians to achieve political ends. The Bhagwan cult sprayed salad bars in Oregon with *Salmonella* in an attempt to influence an election in 1984.[2] The Aum Shinrikyo used the nerve agent sarin in an unsuccessful 1994 assassination attempt on three judges in Matsumoto, Japan. This same group used sarin again in the 1995 Tokyo subway attack that killed 11 people.[3] The United States experienced multiple anthrax hoaxes during 1997 and 1998, motivated by personal or political agendas. Terrorists initiated an actual anthrax attack using the U.S. mail in 2001 that resulted in 11 deaths. No one has yet used radiologic or nuclear devices in a successful mass terrorist attack, but at least one attempt has occurred. In addition, several highly radioactive sources have been stolen from U.S. medical facilities, and a Russian dissident, Alexander Litvinenko, was assassinated with a radiologic agent (polonium-210) in 2006.

Many agents are potential candidates for weaponization, and some represent a substantial risk (Box 194-1). Management strategies for patients exposed to WMD are frequently similar to strategies for hazardous materials exposure. However, several features associated with WMD make these events unique (Box 194-2). Additional knowledge and skills are required in the evaluation and treatment of WMD victims. These plans represent only one small part of an overall comprehensive emergency management strategy for all hazards (see Chapter 193). Names of departments, bureaus, and agencies that can assist with planning and response to WMD events are listed in Table 194-1.

NUCLEAR AND RADIOLOGIC DEVICES

Terrorists selecting radiation as a means to inflict casualties are unlikely to use nuclear weapons. These devices are heavily guarded, difficult to move because of their size and weight, and easy to detect. Although Russia acknowledges that 50 to 100 of its 1-kiloton "suitcase" nuclear weapons are missing, the problems of purchasing, moving, and detonating these devices are formidable. Sabotage at nuclear power stations is possible, but given tight security, multiple safety systems, and thick concrete housings surrounding the reactors, the threat is probably low.

Instead, simple radiologic devices, such as those used by hospitals for radiation therapy, are thought to be the source of choice. These sources are plentiful. They do not detonate on their own and give no warning of their presence unless they are dispersed by a conventional explosive (radiologic dispersal device). Thefts of radiotherapy sources have occurred in the United States. Accidental dispersion from a stolen hospital therapy source in Brazil

www.ketabpezeshki.com 66485457-66963820

resulted in the screening of 112,000 people for contamination. A total of 249 people were found to be exposed, 4 of whom ultimately died.[2] Placement of such a device at an information kiosk in a crowded mall during a busy holiday shopping season would silently expose countless persons to significant radiation.

Ionizing radiation, regardless of its type, causes injury at the cellular level, usually by damaging DNA. Rapidly dividing cells are the most sensitive. Patients have symptoms within hours to days, depending on the dose. Common syndromes associated with radiation exposure include dermal burns, bone marrow failure, and gastrointestinal dysfunction (e.g., vomiting and gastrointestinal bleeding) (see Chapter 146). A U.S. Department of Homeland Security task force developed an expert consensus document on medical treatment of radiologic casualties, and the results were subsequently published in the peer-reviewed literature.[4]

A basic emergency department radiation protocol must address decontamination, triage, staff safety, personal protective equipment (PPE), and diagnostic procedures that emphasize radiation monitoring. Victims presenting to the emergency department will suffer from three types of exposure: irradiation, internal contamination, and external contamination. Irradiated victims have been exposed to a beam of radiation, similar to someone undergoing a chest x-ray examination. They are not radioactive and pose no threat to emergency department personnel.

Contaminated patients are more challenging, and early involvement of the radiation safety officer is critical. This individual evaluates the degree of the victim's contamination and monitors radioactivity levels throughout the decontamination process. Internally contaminated patients present a therapeutic challenge because they have radioactive material inside their bodies (e.g., lungs and gastrointestinal tract) or incorporated into their cells. They should be placed in an isolation room, where all secretions and body fluids can be collected. Various medications are available for administration to internally contaminated patients and can limit uptake or facilitate removal of certain radioactive elements. These medications include Radiogardase (Prussian blue) for cesium and thallium ingestions and diethylenetriaminepentaacetic acid (DTPA) for plutonium exposure. Health care providers can receive assistance by calling the Radiation Emergency Assistance Center/Training Site (REAC/TS; http://orise.orau.gov/reacts) at 865-576-3131 (emergency number: 865-576-1005).

Externally contaminated victims have radioactive material on their skin or clothing and are decontaminated by removal of clothing and washing with soap and water. Washing by protected personnel should continue until monitoring by the radiation safety officer demonstrates the absence of radioactivity. If wounds are present, they are decontaminated first. After the wounds are covered with a sterile, waterproof dressing, the remaining skin is washed. Hospitals must be prepared to decontaminate patients because historical data suggest that up to 80% of patients do not receive this intervention before arrival.[2] Decontamination before hospital entry is crucial because these individuals can expose caregivers to radiation and contaminate the entire hospital through the ventilation system. Removal of clothing and covering of the head with a surgical cap can reduce contamination by 80% to permit stabilization in the decontamination unit, but complete decontamination should occur before exposure of unprotected staff if the patient's medical condition permits.

Initial triage of radiation casualties is based on their overall pathologic condition, not on exposure.[5] Even patients who have received a lethal dose of radiation do not die immediately as a consequence of the ionizing exposure. Therefore, a patient in acute distress from a myocardial infarction or urosepsis would be triaged ahead of a radiation victim with stable vital signs, regardless of the dose received. If a radiation casualty also suffers a severe injury or illness, immediate intervention is required. Most of the immediate morbidity and mortality associated with a radiologic dispersion device is related to traumatic injuries from the explosion and not to radiation exposure.[4]

In addition to patient contamination, the radiation safety officer is responsible for monitoring of the exposure of hospital staff. All personnel involved in the care of contaminated patients

Box 194-1 Potential Agents of High Concern for Use as Weapons of Mass Destruction

Chemical
- Nerve agents
  - Sarin
  - Soman
  - Tabun
  - VX
- Mustard agent

Biologic
- Anthrax
- Plague
- Smallpox
- Botulism
- Viral hemorrhagic fever

Table 194-2 Treatment with Potassium Iodide (KI) for Radioactive Iodine Exposure

SUBPOPULATION	PREDICTED EXPOSURE (cGy)	KI DOSE (mg)	NUMBER OF 130-mg TABLETS
Adults >40 years	>500	130	1
Adults 18-40 years	≥10	130	1
Pregnant and lactating women	≥5	130	1
Children 3-18 years	≥5	65	½
Children 1 month to 3 years	≥5	32	¼
Neonates, birth to 1 month	≥5	16	⅛

should wear dosimeters, which measure the amount of radiation received by the wearer. The safety officer tracks the amount of radiation received by each staff member and can remove a health care worker from the area if the exposure is too high. Radiation monitoring is complex, and the radiation safety officer should be involved as early as possible. Hospitals should consider conducting disaster drills that include casualties suffering radiation injuries.

Although many radioactive elements are candidates for use in a terrorist attack, ^{131}I and related isotopes deserve additional discussion because of heightened interest. ^{131}I is found only after a nuclear detonation or in reactor fuel rods. Although it is not impossible, the probability that terrorists could tap either of these sources is very small. The use of ^{131}I in a radiologic dispersal device is unlikely because of its short half-life (8 days). Even if such a device could be made, it is extremely unlikely that the radiologic dispersal device could disperse sufficient radioactive material to pose an immediate health hazard.[6] Given these facts, the probability that any significant exposure of the population (especially children) to ^{131}I will occur is equally small. The large number of childhood thyroid cancers that occurred after the accident at the Chernobyl nuclear power plant resulted, to a significant degree, from situations that will not occur in the United States. These include delayed reporting of a breach in the reactor containment vessel preventing timely evacuation of all exposed populations, failure to effectively quarantine contaminated milk and vegetables, and significant iodine deficiency in the exposed population.[7] The risk to children in communities surrounding the Fukushima nuclear power plant is also an issue that will require long-term monitoring. Nonetheless, concern about treatment to prevent thyroid cancer after potential exposure to ^{131}I remains. Current recommendations for treatment with potassium iodide, which blocks uptake of ^{131}I by the thyroid, are listed in Table 194-2. Caveats for use of this table include increasing the amount of potassium iodide for adolescents approaching 70 kg to the adult dose (130 mg) and monitoring thyroid-stimulating hormone and free T_4 levels in neonates when possible. Nonpregnant adults older than 40 years are unlikely to benefit from this intervention.

BIOLOGIC WEAPONS

By convention, biologic weapons are divided into three groups: bacteria, viruses, and toxins. A characteristic shared by these agents is their ability to be dispersed as an aerosol. Because this is the most effective means to expose a large population, aerosol dispersal is the most likely route that terrorists will use to deploy such weapons. Therefore, victims will have respiratory signs and symptoms. Dermal contact and ingestion are also potential pathways for exposure, and some agents are effective by these routes. People infected in the 2001 U.S. anthrax attack were inoculated through aerosol and dermal exposures. However, it is logistically more difficult to produce large casualty numbers by nonrespiratory portals of entry, so agents spread primarily by injection or through the gastrointestinal tract are less likely candidates for wide deployment. If the goal is to disrupt the economy or to spread fear among the population, then almost any type of release will suffice, whether or not people actually die.

Box 194-3 Signs Suggesting Biologic Weapon Deployment

Syndromes
Pulmonary symptoms, pneumonia
Rashes
Sepsis syndrome
Influenza symptoms

Epidemiology
Multiple, simultaneous events
Dead animals
Large numbers of patients with high toxicity and death rate

Patients exposed to biologic agents usually present with vague symptoms associated with an influenza-like illnesses. Unless a biologic attack is announced or suspected, the emergency department staff may not realize that they are treating victims. Indeed, it is not always possible to distinguish natural occurrences from engineered outbreaks of diseases. Examples of non-terrorist outbreaks of anthrax include cutaneous disease in intravenous heroin users in Europe and an outbreak of cutaneous anthrax in Bangladesh in 2010 with more than 400 cases. Because of the challenges in identifying the true etiology of acute events, personnel should be vigilant and at least consider the possibility, especially when warning signs are present (Box 194-3). For example, large numbers of patients suddenly presenting with "the flu" not during influenza season should cause concern. For these reasons, health surveillance will be paramount in identifying agents and potential sources. The emergency department should have a working relationship with local and state health departments as well as with local law enforcement and stay apprised of Centers for Disease Control and Prevention (CDC) and Department of Homeland Security guidelines.

Several infectious agents with potential for use as biologic weapons can spread in a hospital environment. Examples include Ebola and smallpox.[2,8] Hospitals need protocols for PPE and patient isolation to ensure a safe environment.[9-12] Fortunately, such protocols are similar to those applied to other infectious diseases (Box 194-4). Implementation of such precautions is credited with halting of the in-hospital spread of the Ebola virus in the 1995 Zaire outbreak. Decontamination is not a priority unless the exposure is immediate. Standard (universal) precautions are generally sufficient, and special suits (e.g., levels A, B, and C) are unnecessary.[13]

Whereas the CDC lists six Category A (high threat) agents (www.bt.cdc.gov/agent/agentlist-category.asp), this chapter

www.ketabpezeshki.com 66485457-66963820

Box 194-4 Recommendations for Prevention of In-Hospital Transmission of Contagious Agents

Isolate patient in single room with adjoining anteroom.
Have handwashing facilities and personal protective equipment available in anteroom.
Use negative air pressure if possible.
Use strict barrier precautions: personal protective equipment, gowns, gloves, HEPA filter respirators, shoe covers, protective eyewear.
Alert hospital departments that generate aerosols: laboratory (centrifuges), pathology (autopsies).

focuses on three biologic agents—anthrax, plague, and smallpox—that represent the greatest interest.[14]

Anthrax

Bacillus anthracis, a gram-positive spore-forming bacterium, is the causative agent of anthrax ("woolsorter's disease"). The spores are extremely hardy and can survive for years in the environment. The disease is caused by exposure to the spores, not the bacilli in their vegetative state. It is normally a disease of sheep, cattle, and horses and is rarely seen in developed countries because of animal and human vaccination programs. Disease in humans can occur when spores are inhaled, ingested, or inoculated into the skin. The spores germinate into bacilli inside macrophages. The bacteria then produce disease by releasing toxins (e.g., protective antigen, edema factor, and lethal factor) that cause edema and cell death.

Russia and the United States have developed anthrax into a biologic weapon. The effectiveness of this agent was clearly demonstrated by two events: an accidental release of spores from a biologic weapons facility in the former Soviet Union town of Sverdlovsk in 1979 and the intentional distribution of anthrax spores through the mail along the eastern seaboard of the United States in 2001. After the Sverdlovsk release, at least 66 people died downwind from the compound during the next several weeks, and animal cases of anthrax were reported 30 miles away.[15,16] The ability of non–state-sponsored terrorist groups to develop anthrax as a weapon is uncertain. The Japanese organization Aum Shinrikyo made several attempts to disperse anthrax throughout Tokyo without success.[1] The individual believed responsible for the U.S. anthrax attack was not a foreign national. This is consistent with the fact that the strain of anthrax used in the attack (Ames strain) was developed by the U.S. government.

Inhalational anthrax is the most lethal form of the disease and is caused by inhalation of spores into the lungs. The mortality rate was thought to exceed 90%. However, data from the 2001 anthrax exposure call this figure into question (5 deaths in 11 cases). Although the actual mortality rate is unknown, it is probably in the 50% range.[17,18] The minimum number of spores required to produce disease is unknown. The original number quoted in the literature, 10^4 spores, appears high given recent experience.[19] After phagocytosis by macrophages, the spores germinate and are transported to the tracheobronchial lymph nodes, where the bacteria multiply. During 2 to 10 days, patients have an influenza-like illness, with malaise, fever, and nonproductive cough. This initial phase can be delayed for more than 1 month in some patients. Within 24 to 48 hours, abrupt deterioration occurs, with overwhelming sepsis, shock, hemorrhagic mediastinitis, dyspnea, and stridor. A chest radiograph obtained at this time may show a widened mediastinum and hilar adenopathy, but typical radiographic findings are not dramatic and could be missed (Fig. 194-1). Computed tomography scanning of the chest is more sensitive and should be performed if the disease is suspected. Bloody pleural effusions can also occur, and examination of the lung fields

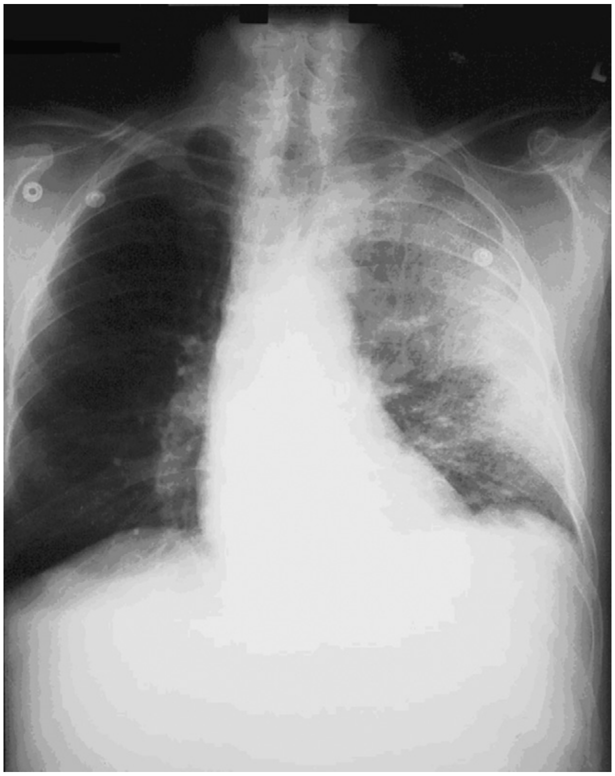

Figure 194-1. Chest radiograph of anthrax patient showing diffuse left lung consolidation consistent with pneumonia. There is no mediastinal widening. (Courtesy the U.S. Centers for Disease Control and Prevention.)

Figure 194-2. Chest computed tomography scan of an anthrax patient showing pulmonary consolidation and effusions. (Courtesy the U.S. Centers for Disease Control and Prevention.)

frequently reveals consolidation. This can easily be confused with pneumonia (Fig. 194-2). Death usually results within 3 days, and 50% of patients have hemorrhagic meningitis. Human-to-human transmission has not been reported with inhalational anthrax.

Initial diagnosis is generally made clinically on the basis of an influenza-like or septic illness; a suspicious chest radiograph or computed tomography scan demonstrating hilar adenopathy,

www.ketabpezeshki.com 66485457-66963820

Figure 194-3. Adult with cutaneous anthrax. (Courtesy the U.S. Centers for Disease Control and Prevention.)

infiltrates, or pleural effusions; and a reason to consider anthrax in the first place (e.g., current outbreak or warning from authorities). Several clinical algorithms exist that attempt to separate patients with influenza from those with anthrax.[20,21] Unfortunately, they are based on a handful of anthrax cases, and their usefulness remains in doubt.[18] Sputum culture, Gram's stain, and blood cultures are not helpful until late in the course of the disease. Tests to confirm the diagnosis of inhalational anthrax include the polymerase chain reaction for identification of anthrax markers in pleural fluid, serologic detection of immunoglobulin to protective antigen, and immunohistochemical testing of biopsy specimens.

In addition to inhalational anthrax, cutaneous anthrax can occur in any area where large numbers of spores are released, as was the case in the United States in 2001. This form of the disease occurs when spores are introduced into the skin, usually through open wounds or abrasions. The mortality rate is approximately 20% without treatment and 1% with treatment. Antibiotics do not affect the course of local disease but are used to prevent dissemination and death. After an incubation period of 1 to 5 days, a papule develops, progressing to form a large vesicle during the next several days. Severe edema occurs around the lesion and is associated with regional lymphadenitis. The lesions are not tender, and the patient may or may not be febrile (Fig. 194-3). After approximately 1 week, the lesion ruptures, forming a black eschar (thus the name *anthrax,* from the Greek word for "coal"). In the next 2 or 3 weeks, either the eschar sloughs off and the illness is over or the organism disseminates and the patient dies. As with inhalational anthrax, the diagnosis is predominantly clinical. Confirmation is established by culture of the lesion, punch biopsy, or serologic testing. A total of 11 cutaneous anthrax cases occurred in the United States after the 2001 attack.[22]

A few cases of gastrointestinal anthrax and oropharyngeal anthrax are also possible after a terrorist attack. These rare manifestations usually occur with the ingestion of insufficiently cooked, contaminated meat. The mortality rate is approximately 50%. After ingestion, the spores are transported to regional lymphatic tissue, where symptoms develop after a 2- to 5-day incubation period. Patients with oropharyngeal anthrax present with sore throat and neck swelling from cervical and submandibular lymphadenitis. The tonsils are also frequently involved, and symptoms are associated with fever and toxicity. Dysphagia and respiratory distress often follow. Gastrointestinal anthrax begins with nausea, vomiting, and fever associated with mesenteric lymphadenitis. Patients then experience severe abdominal pain, hematemesis, ascites, and bloody diarrhea and may present with an acute abdomen.

Box 194-5 Treatment of Anthrax

Cutaneous Anthrax *without* Toxicity

Adults

Ciprofloxacin, 500 mg PO bid
or
Doxycycline, 100 mg PO bid
or
Amoxicillin, 500 mg PO tid

Children

Ciprofloxacin, 20-30 mg/kg/day PO divided bid (max. 1 g)
or
Doxycycline, 4.4 mg/kg/day PO divided bid (max. 200 mg)
or
Amoxicillin, 20-40 mg/kg/day PO divided tid (max. 1500 mg)
All doses are given for 7-10 days.

Inhalational, Cutaneous, or Gastrointestinal Anthrax *with* Toxicity

Adults

Ciprofloxacin, 400 mg IV q12h
or
Doxycycline, 100 mg IV q12h
or
Penicillin G, 4 million units IV q4h

Children

Ciprofloxacin, 20 mg/kg/day IV divided q12h (max. 800 mg)
or
Doxycycline, 4.4 mg/kg/day IV divided q12h (max. 200 mg)
or
Penicillin G, 100,000-400,000 units/kg/day IV divided q4h (max. 24 million units)

All doses are given until toxicity resolves, then switch to oral form. Treat for 60 days or until the patient receives three doses of vaccine.

Postexposure Prophylaxis

The same drugs and dosage are prescribed as for cutaneous anthrax without toxicity. Treat for 60 days or until the patient receives three doses of vaccine.

Treatment

Traditional treatment of anthrax infection has been penicillin. However, weapons-grade anthrax is probably resistant to penicillin (although this was not the case with the U.S. attack). Current treatment recommendations reflect this fact (Box 194-5).[1,2] These consensus recommendations include fluoroquinolones and tetracycline for all children, regardless of age. Balancing the potential risks of such drugs against the consequences of infection by drug-resistant anthrax strains, the benefits justify the recommendations. Nontoxic victims with cutaneous anthrax can be treated as outpatients with oral ciprofloxacin or doxycycline for 7 to 10 days. Victims with inhalational, cutaneous, or gastrointestinal disease and toxicity require intravenous therapy with ciprofloxacin or doxycycline plus at least two other antibiotics (e.g., rifampin, clindamycin, imipenem, or an aminoglycoside). Patients can be switched to oral antibiotics when toxicity resolves. Other modalities that may be helpful include chest tube drainage of pleural effusions and possibly tracheal intubation and mechanical ventilation.[22] Surprisingly, the latter intervention did not improve mortality. All patients intubated after the U.S. anthrax attack died.[17,19]

Treatment must continue for 60 days or until the patient has received three doses of the anthrax vaccine, given on days 0, 14,

www.ketabpezeshki.com 66485457-66963820

and 28. The complete vaccine course requires 18 months. This treatment regimen is also recommended for children and pregnant women. If the anthrax strain proves susceptible, patients can be switched to intravenous penicillin or oral amoxicillin. In vitro studies suggest that ofloxacin or levofloxacin can be substituted for ciprofloxacin.[1]

For postexposure prophylaxis, oral ciprofloxacin (500 mg) or doxycycline (100 mg) twice a day is recommended. Amoxicillin can be substituted if sensitive strains are identified. Antibiotic prophylaxis must continue for 60 days or until patients have received at least three doses of the vaccine. The vaccine is approved by the U.S. Food and Drug Administration (FDA) for adults but not for children. A review by the Institute of Medicine found the vaccine both safe and effective for prophylaxis against inhalational anthrax.[23]

Plague

Plague has been a human pathogen since antiquity. Many regions of the world, including Asia and India, are currently witnessing the third pandemic of plague, and this affliction is endemic in the western half of the United States. Plague is caused by *Yersinia pestis,* a gram-negative bacillus. It is normally a disease of rodents that is transmitted to humans through the bite of an infected flea or by inhalation. Three forms of the disease exist: pneumonic, bubonic, and septicemic plague. The bacteria do not form spores and die rapidly in the environment. However, they are viable for days in dry sputum, flea feces, and human remains. Dogs are relatively resistant to infection, but cats are highly susceptible and could form a reservoir for maintaining the disease in a human population. Recovery is followed by temporary immunity.

Primary pneumonic plague results when bacilli are inhaled into the lungs. It has a mortality rate approaching 100% if it is not treated early. Pneumonic plague will be the most frequently encountered form of the disease because terrorists are likely to use aerosolization as the method of dispersal. After an incubation period of 2 or 3 days, victims have sudden onset of fever, chills, and an influenza-like illness. This is followed within 24 hours by a fulminant pneumonia associated with hemoptysis, systemic toxicity, respiratory failure, circulatory collapse, and death. The pneumonia is classically lobar, but any x-ray pattern is possible, including acute respiratory distress syndrome. Six percent to 10% of victims have plague meningitis. Coagulation abnormalities and hepatocellular injury occur. The coagulopathy is characterized by ecchymoses, disseminated intravascular coagulation, and acral gangrene (“black death”). The gangrene is caused by bacterial production of the coagulase enzyme in areas of the body where the temperature drops below 37°C. This causes blood to clot in fingers, toes, and the nose, with resultant infarction and gangrene. If the victims survive, long-term rehabilitation is required. Pneumonic plague is transmissible human to human.

Bubonic plague occurs when organisms are inoculated into the skin, usually from a flea bite. During the 2- or 3-day incubation period, the bacilli migrate to regional lymph nodes, where they multiply and cause inflammation and necrosis of lymphatic tissue, resulting in large, tender nodes, or buboes. Typically, buboes develop in the groin, axilla, or cervical region and are so painful that the patient will refrain from moving the affected area (Fig. 194-4). Individuals experience fever, chills, and weakness. In approximately 25% of patients, vesicles or ulcerations occur at the site of the flea bite. The buboes are usually nonfluctuant but rarely can suppurate. Organisms can be aspirated from the nodes for diagnosis, but incision and drainage are not recommended because the lymphadenitis resolves with antibiotic treatment, and practitioners could become infected if they are exposed during the procedure.

Figure 194-4. Child with bubonic plague demonstrating axillary bubo. (Courtesy Frederick M. Burkle, Jr., MD, MPH.)

During the next week or more, the bacteria disseminate in approximately 50% of patients with bubonic plague. These victims have septicemic plague or secondary pneumonic plague and die if they are untreated. Those with septicemic plague experience endotoxemia, shock, disseminated intravascular coagulation, and coma. If bacteremia does not occur, most victims recover. A small percentage of those infected by fleas have septicemic plague without detectable buboes. Direct human-to-human transmission does not occur with bubonic or septicemic plague. However, both of these conditions can lead to secondary pneumonic plague, which is communicable. Therefore, initial isolation (for the first 48 hours) is recommended for all patients with plague.

Differential Diagnosis

The preliminary diagnosis of plague is clinical. Few diseases other than plague cause fulminant gram-negative pneumonia associated with hemoptysis in previously healthy individuals. The same can be said for diseases that cause lymphadenopathy. Cat-scratch disease, tularemia, and staphylococcal or streptococcal infections are all in the differential diagnosis. However, the extremely tender nature of the lymphadenopathy and the toxicity of the patient strongly suggest plague. Once the disease is suspected, Gram's stain and culture of sputum, blood, cerebrospinal fluid, or lymph node aspirate are helpful. State health departments or the CDC can test specimens for the presence of the capsular antigen by direct fluorescent antibody staining. Polymerase chain reaction also holds promise. Unfortunately, all laboratory tests require several days to complete, so initial management decisions must be based on clinical findings.

Treatment

Antibiotic treatment is essentially identical for all three types of plague (Box 194-6).[24] The same caveats for the use of fluoroquinolones and tetracycline in children with anthrax apply to plague. In the case of pneumonic and septicemic plague, treatment should be started within 24 hours of symptoms for outcome to be improved. Antibiotics are given for a minimum of 10 days. As patients improve, oral antibiotics are substituted for intravenous therapy to complete the course. Respiratory isolation of patients with pneumonic plague is necessary for 4 days after beginning of antibiotics to guarantee sterilization of sputum. Patients with septicemic and bubonic plague require isolation for 48 hours. If they do not have pneumonia or draining lesions during this time, isolation can be discontinued. Nonseptic patients with mild bubonic plague can be treated at home with oral doxycycline or tetracycline for 10 days.

Box 194-6 Treatment of Plague

Parenteral Therapy
Adults
Streptomycin,* 1 g IM bid
Gentamicin, 5-7 mg/kg once daily IM or IV
Doxycycline, 100 mg IV bid
Ciprofloxacin, 400 mg IV bid
Chloramphenicol, 25 mg/kg IV qid

Children
Streptomycin,* 15 mg/kg IM bid (max. 2 g/day)
Gentamicin, 2.5 mg/kg IM or IV tid
Doxycycline, 2.2 mg/kg IV bid (max. 200 mg/day)
Ciprofloxacin, 10 mg/kg IV bid (max. 800 mg/day)
Chloramphenicol, 25 mg/kg IV qid

Pregnant women
Same as above but exclude streptomycin and chloramphenicol

Oral Therapy
Adults
Doxycycline, 100 mg bid
Ciprofloxacin, 500 mg bid
Chloramphenicol, 25 mg/kg qid

Children
Doxycycline, 2.2 mg/kg bid (max. 200 mg/day)
Ciprofloxacin, 15 mg/kg bid (max. 1 g/day)
Chloramphenicol, 25 mg/kg qid

Pregnant women
Same as above but exclude chloramphenicol

*Although streptomycin is recommended as first-line treatment, it may not be readily available.

The mainstay of prophylaxis against plague remains oral antibiotics. A vaccine exists but has no value in an acute outbreak. It is effective only against bubonic disease and requires several months to impart immunity. The drugs for prophylaxis are tetracycline, doxycycline, ciprofloxacin, chloramphenicol, and possibly trimethoprim-sulfamethoxazole for children.

Smallpox

Smallpox was eradicated in 1980. The only known repositories of the variola virus, the etiologic agent of smallpox, are in the United States and Russia. However, Russia was successful in weaponizing the virus, which may have been sold or smuggled out of the country.[8] The effectiveness of Russia's weaponized strain was demonstrated in 1971 when an individual became infected while traveling on a ship 15 km downwind from a Soviet bioweapons test site (Vozrozhdeniye Island in the Aral Sea).[25] In addition, most of the world's population is no longer fully immune to infection because vaccination against smallpox ceased approximately 40 years ago in nonmilitary personnel. Given its high infectivity and lethality, this makes smallpox an excellent biologic weapon.

The variola virus is spread as an aerosol. It can survive for 24 hours, and possibly 48 hours, in the environment. The occurrence of smallpox in hospital employees whose only exposure was handling of laundry from infected people is testimony to its viability. Approximately 30% of exposed people become ill. One infected person has the potential to infect up to 20 other individuals. People are infectious from the time the rash first appears until the scabs fall off (1 or 2 weeks). Anyone exposed to smallpox should be quarantined and observed for 17 days to rule out infection.

The disease is manifested clinically in several forms. Variola major and variola minor represent 90% of the cases. Variola major is the classic form, a more severe illness with a mortality rate of 30%. Variola minor is a milder form, with less toxicity, fewer pox, and a mortality rate of 1%. Two other forms of the disease, hemorrhagic and malignant (or flat) smallpox, are seen in 10% of cases; the mortality rate is greater than 90%. Patients with hemorrhagic smallpox have symptoms earlier and become toxic quickly. Instead of pox, their rash is characterized by petechiae and hemorrhage. Death occurs in 5 or 6 days. Those with malignant smallpox have a similar course, but their rash is characterized by soft, flattened lesions that never progress to pustules. If they survive, the lesions resolve without forming scabs.

Figure 194-5. Man with smallpox. (From the U.S. Centers for Disease Control and Prevention Public Health Image Library.)

The infection begins when the virus is inhaled. After migrating to regional lymph nodes, the virus replicates for 3 or 4 days and then asymptomatically spreads to the spleen, bone marrow, other lymphoid tissue, and liver. A second viremia occurs 8 to 12 days later and is associated with fever, prostration, and headache. Mental status changes can occur. During this phase, which lasts 2 or 3 days, the virus localizes to the skin and pharyngeal mucosa. A maculopapular rash soon appears, which becomes vesicular and finally pustular. In contrast to chickenpox, the rash first appears on the face and forearms, later spreading to the legs and trunk. All the lesions in any one area of the body are the same age (Fig. 194-5). During the next 8 to 14 days, the pustules crust over and separate from the skin, leaving pitted scars.

A clinical algorithm developed by the CDC can assist in assessing the probability that an individual has smallpox. It relies on three major and five minor criteria. The major criteria are a febrile prodrome, classic smallpox lesions, and lesions in the same stage of development. The minor criteria are centrifugal distribution of pustules; first lesions on the oral mucosa, face, or forearms; toxic appearance; slow evolution of lesions; and pustules on the palms and soles. A patient with all three major criteria is at high risk and should be isolated and reported to public health authorities and law enforcement agencies immediately. Patients with the febrile prodrome and either four minor criteria or one other major criterion are at moderate risk. Consultation with infectious disease and dermatology specialists should be sought and tests ordered to confirm varicella. If smallpox cannot be ruled out after these interventions, the patient should be treated as high risk. If a patient does not have the febrile prodrome or has the prodrome but no other major criteria and has fewer than four minor criteria, the individual is at low risk for smallpox. These patients can be managed as clinically indicated.[26]

Differential Diagnosis

As with anthrax and plague, the initial diagnosis of smallpox is clinical. Other illnesses resembling smallpox include chickenpox,

www.ketabpezeshki.com 66485457-66963820

herpes simplex, and monkeypox. Unlike with variola, the rash associated with chickenpox (varicella) is seen first on the trunk and then spreads to the extremities and face. In addition, the pustules are in different stages of evolution in any one area of the body. If the first case seen is hemorrhagic or malignant smallpox, the diagnosis will probably be missed until more typical cases present. For confirmation of the diagnosis, vesicular fluid or scabs were traditionally sent for electron microscopic examination. Polymerase chain reaction techniques appear promising for rapid viral identification, with sensitivities and specificities in the 98% range.[27]

Treatment

No effective therapy exists for victims infected with smallpox who become symptomatic. However, potential antiviral agents, such as cidofovir, show promise. In mice exposed to a lethal cowpox challenge, administration of an oral lipid prodrug of cidofovir in modest doses once a day for 5 days produced 100% survival.[28] Vaccinia immune globulin (VIG) has no role in the treatment of active disease. Some practitioners suggest that most smallpox patients should be isolated at home or other nonhospital facilities because the virus spreads easily in a hospital environment and the disease is currently untreatable.[8]

The best strategy for containment of the disease is vaccination of the susceptible population. Vaccination of an immunocompetent individual within 3 days of exposure will prevent or significantly ameliorate illness. Vaccination up to 7 days after exposure may prevent death. Complications from vaccination with vaccinia virus occur and can be fatal. Groups at risk for these adverse consequences include pregnant women and people with eczema, human immunodeficiency virus infection, and immunosuppressive conditions (e.g., malignant disease, chronic steroid use, and hereditary immunodeficiencies). Given the seriousness of the disease, the current recommendation is to vaccinate these individuals if there is risk of exposure and simultaneously administer 0.3 mL/kg of VIG intramuscularly. For people who have complications from the vaccine (e.g., progressive vaccinia, ocular autoinoculation, and eczema vaccinatum), the dose of VIG is 0.6 mL/kg intramuscularly and is divided during 24 to 36 hours. Ribavirin can be administered but is considered experimental. VIG is not indicated for vaccinia-associated encephalitis.

The smallpox vaccine supply situation has improved dramatically in the United States. The CDC has 100 million doses of the traditional smallpox vaccine (Dryvax). These vials can be diluted 5 : 1 to produce a total of 500 million doses without any decrement in the vaccine's efficacy.[29] In 2004, a British company delivered an additional 209 million doses of a second-generation vaccine derived from the same vaccinia virus used in Dryvax but grown in cell cultures. In addition, work is commencing on production of an improved modified vaccinia Ankara vaccine. The virus used in the modified vaccinia Ankara vaccine is so attenuated that it does not replicate in a human host. This may make it safe for administration to immunocompromised individuals.

CHEMICAL WEAPONS

Unlike victims of biologic weapons, casualties exposed to chemical agents manifest symptoms quickly, from immediately to a few hours after chemical contact.[30] Therefore, surveillance and recognition are less problematic. The challenge is decontamination and treatment.

Terrorism with chemical weapons produces casualties similar to those seen in hazardous materials incidents, and medical management is comparable. However, the unique features of such events, including the volume of patients and the risk of hospital contamination, necessitate additional preparation. For example, the Tokyo subway attack with use of sarin in 1995 resulted in 11 deaths and more than 5000 patients converging on local emergency departments. Although the majority of these patients had subclinical exposure or psychological symptoms alone, the health care system was severely stressed. Secondary contamination by direct contact or vaporization occurred in ambulances and at the hospitals.[3]

Box 194-7 Emergency Department Preparedness for Chemical Weapons of Mass Destruction

- Community-based hospital planning
- Personnel trained in recognition, mass casualty triage, and treatment
- Decontamination facility with protocols (e.g., runoff water, warm water)
- Personal protective equipment readily accessible and compliant with regulations
- Rapid access to antidotes, cyanide kits, and anticonvulsants
- Hospital incident management system in place
- Knowledge of how to access experts quickly

Health care facilities should have protocols in place to deal with the eventuality of chemically contaminated patients (Box 194-7).[31,32] Current recommendations for levels of PPE and types of decontamination facilities necessary in a hospital setting have been advanced, but evidence-based recommendations remain inconclusive.[33,34] Collection of waste water from the decontamination process in a containment vessel is ideal but not required if this would impede necessary and appropriate actions to protect human life (www.epa.gov/oem/docs/chem/runoff.pdf).

The four basic classes of chemical agents are nerve, vesicant (blistering), blood, and pulmonary (choking). Although all have potential for use as weapons, the nerve agents and vesicants are thought to represent the greatest threat.

Nerve Agents (Sarin, Tabun, Soman, and VX)

Nerve agents are organophosphates. They inhibit the enzyme acetylcholinesterase, blocking the degradation of acetylcholine at the postsynaptic membrane. Acetylcholine accumulates, resulting in overstimulation of muscarinic and nicotinic receptors. Symptoms are receptor dependent. Stimulation of muscarinic receptors produces miosis, salivation, rhinorrhea, lacrimation, bronchorrhea, bronchospasm, vomiting, and defecation. The major life threat associated with this syndrome is ventilatory compromise from profound bronchorrhea and bronchoconstriction. Stimulation of nicotinic receptors produces muscle fasciculations, flaccid paralysis, tachycardia, and hypertension. Unlike with typical organophosphates, exposure to nerve agents has not been associated with urination. In addition, bradycardia is rare, and miosis does not respond to systemic therapy.[2]

Nerve agents also cause direct central nervous system toxicity that is manifested as seizures, coma, and apnea. In survivors, residual central nervous system effects are manifested as psychological changes that can last 4 to 6 weeks. These manifestations are caused by chemical effects, not stress.

A preliminary diagnosis of nerve agent exposure is based on clinical findings. Important features include muscle fasciculations and miosis, which are sufficient to justify treatment pending further evaluation. Diagnosis is confirmed by measurement of red blood cell cholinesterase levels. This test is not readily available, however, so treatment must begin before test results are known.

Terrorists are most likely to use the nerve agents sarin (designated GB) and VX. Sarin exists as a liquid at room temperature but represents primarily a vapor threat because of its high volatility. Symptoms occur within seconds after inhalation of vapor and

www.ketabpezeshki.com 66485457-66963820

Box 194-8 Type and Degree of Nerve Agent Exposure

Vapor Exposure (Sarin)
Mild: rhinorrhea and miosis
Moderate: mild symptoms plus increased secretions, wheezing or dyspnea, muscle weakness or fasciculations, or gastrointestinal effects
Severe: apnea, seizures, loss of consciousness, flaccid paralysis, or major involvement of two organ systems

Liquid Exposure (VX)
Mild: localized sweating and fasciculations where a drop touches the skin; no miosis; may be delayed for 18 hours
Moderate: gastrointestinal effects; miosis uncommon; may be delayed for 18 hours
Severe: apnea, seizures, loss of consciousness, flaccid paralysis, or major involvement of two organ systems; occurs in less than 30 minutes at or above LD_{50}

peak at 5 minutes. There are no delayed effects; patients remaining asymptomatic 1 hour after possible chemical contact have not received a clinically significant exposure. They can be sent home. VX is a thick liquid with low volatility. It represents a liquid threat only. In general, victims have symptoms after skin exposure. The median lethal dose (LD_{50}) for VX is 10 mg, a droplet slightly larger than a pinhead. Death from doses of this size occurs in less than 30 minutes. Delayed symptoms occur, so individuals must be observed for 18 hours before potential intoxication can be ruled out.

Decontamination of victims exposed to sarin vapor requires only removal of clothing. People contaminated with VX or liquid sarin should have their clothing removed and then must be decontaminated by use of showers. When the level of exposure or the involved agent is uncertain, full decontamination is prudent. Responders caring for patients in the presence of liquid sarin exposure may require level A or B protective suits.

Treatment

The treatment of nerve agent victims depends on the form (liquid or vapor) and level of exposure (mild, moderate, or severe) (Box 194-8). Three drugs are the mainstay of treatment: atropine for the muscarinic effects (improves ventilation), pralidoxime chloride (2-PAM) for the nicotinic effects (reverses paralysis), and diazepam for the prevention and treatment of seizures (Box 194-9). The dose of atropine is titrated to the drying of respiratory secretions and not to heart rate or pupil size. If diazepam is unavailable, other benzodiazepines can be used. 2-PAM is most effective if it is administered within 4 to 6 hours of sarin exposure. After this period, the drug's impact wanes because of "aging," defined as the permanent attachment of sarin to the acetylcholinesterase enzyme. Hypertension can occur during 2-PAM administration and is controlled by intravenous phentolamine, 5 mg for adults and 1 mg in repeated doses for children. Recently, investigators have published data that question the efficacy of oximes in the treatment of commercial insecticide exposure. In one study, the use of oximes did not improve clinically important outcomes.[35] Whether these results apply to nerve agents remains uncertain.

An autoinjector kit (Mark I) approved by the FDA consists of two cartridges, one containing atropine (2 mg) and the other 2-PAM (600 mg). Mark I kits are available as part of civilian pharmaceutical caches strategically located throughout the United States. A newer version with both drugs combined in a single autoinjector (Antidote Treatment Nerve Agent Auto-Injector referred to as DuoDote) will gradually replace the Mark I kits. An autoinjector containing 10 mg of diazepam is an additional option if intravenous access is not possible. Doses should be adjusted for pediatric and geriatric patients. Atropine autoinjectors are manufactured in three doses (2 mg, 1 mg, and 0.5 mg) for these groups. Use of the Mark I kits to treat children and the elderly can be problematic because of difficulty in adjusting the dose. An alternative solution is to inject the medication into a sterile vial. The drug can then be reaspirated in an appropriate amount for the patient's weight or age and administered.[36]

Box 194-9 Treatment of Nerve Agent Exposure* Vapor

Mild: *Observe for 1 hour,* then release; no treatment
Moderate:
- One or two Mark I kits IM *or*
- Atropine, 2-4 mg IV, may repeat every 5-10 minutes as needed; *and* 2-PAM, 1 g IV during 30 minutes, may repeat every hour as needed

Severe:
- Three Mark I kits IM and one diazepam autoinjector IM *or*
- Atropine, 6 mg IV, may repeat 2-mg boluses IV every 5-10 minutes; *and* 2-PAM, 1 g IV during 30 minutes, repeat every hour for total of 3 g; *and* diazepam, 5 mg IV, may repeat as needed

Liquid
Mild:
- One Mark I kit IM *or*
- Atropine, 2 mg IV, *and* 2-PAM, 1 g IV during 30 minutes

Moderate: Same as for vapor
Severe: Same as for vapor

Pediatric Doses
Atropine, 0.02 mg/kg IV
2-PAM, 20-40 mg/kg IV during 20-30 minutes
Diazepam, 0.2-0.3 mg/kg IV

*Give atropine before attempting intubation. Otherwise, airway resistance will inhibit ventilation. Continue atropine until secretions are dry (usually 20 mg). In hypoxic patients, IV atropine has been reported to cause ventricular fibrillation, so consider use of IM atropine.

Vesicants (Mustard)

Vesicants (blistering agents) are chemical warfare agents that induce blister formation on contact with skin. Terrorists could use several of these compounds, but mustard is considered the chemical of choice. Mustard is a liquid at room temperature but has both liquid and vapor toxicity. Injury from mustard exposure occurs in 1 or 2 minutes, but symptoms do not develop for 4 to 8 hours. The exact mechanism is unknown, but the agent damages DNA, causing eventual cell death. Mustard has both local and systemic toxicity. Local effects occur from direct exposure to the skin, eyes, and airway. Systemic effects result from the impact of absorbed mustard on the bone marrow. Treatment is supportive and includes decontamination (to prevent secondary contamination) and airway maintenance. Although no specific antidote for mustard is currently available, a topical iodine preparation shows promise. When it is applied within 1 hour after mustard exposure to the skin of guinea pigs, an iodine-tetraglycol solution reduced vesicle formation and signs of inflammation.[37] Application of the solution more than 1 hour after exposure was not effective in preventing symptoms.

Eye damage from mustard exposure varies from conjunctivitis to corneal ulcer and perforation; however, only 1% of patients have permanent eye damage. Severe pain is frequently associated with mustard injury and causes significant blepharospasm. Irrigation is beneficial if it is performed within minutes of exposure but ineffective once symptoms occur. Standard treatment includes

www.ketabpezeshki.com 66485457-66963820

mydriatics, topical antibiotics, oral analgesics, and petroleum jelly applied to the lids to prevent adhesions. Topical steroids are indicated only within the first 24 hours.

The hallmark of mustard injury is skin blisters resembling second-degree burns. Within 4 to 8 hours of exposure, erythema and burning occur, followed by vesicle and bulla formation. Most vapor injuries do not involve the entire dermis, so wounds will not require skin grafting. If liquid exposure occurs to skin, full-thickness burns may result. The patient should be decontaminated by removal of clothing and washing with water or a dilute bleach (1 : 10 hypochlorite) solution. More concentrated bleach solutions are contraindicated as they can cause skin damage. Decontamination immediately after exposure prevents further injury to the patient, but delayed decontamination is indicated to protect staff. Treatment is supportive and includes standard burn wound management, analgesia, and tetanus prophylaxis. An important exception is fluid resuscitation. Fluid losses from mustard injury are much less than those associated with thermal burns. Therefore, standard burn formulas for fluid administration do not apply, and caution should be used to avoid overhydration.

The degree of airway injury after mustard exposure is dose dependent. Mild exposure causes irritation of the nose, sinuses, and pharynx and can be treated with cool, humidified mist. Moderate exposure extends to the larynx and upper trachea and may require treatment with oxygen, continuous positive airway pressure, or even intubation. Severe exposure involves the lungs, producing hemorrhagic necrosis of the bronchioles. Pulmonary edema is rare. Intubation is usually required, and patients may benefit from positive end-expiratory pressure and in-line bronchodilators. Steroids are of questionable benefit, and antibiotics should be given only for established infection.

Systemic toxicity from mustard is caused by bone marrow suppression. Absorbed mustard kills stem cells, causing the white blood cell count to decline after 3 to 5 days. Survival is rare if the white blood cell count falls below 200, which generally occurs when more than 50% of the total body surface area is involved from exposure to liquid agent. Death after mustard exposure usually results from secondary infection.

Blood Agents (Cyanide)

Blood agents such as cyanide bind to cytochromes within mitochondria and inhibit cellular oxygen use. Low-dose exposures result in tachypnea, headache, dizziness, vomiting, and anxiety. Symptoms subside when the patient is removed from the source. At higher doses, the symptoms progress to seizures, respiratory arrest, and asystole within minutes of exposure.

Victims should be removed from the area, have their clothing discarded, and receive oxygen. If no improvement occurs, the cyanide antidote is given. This has traditionally been the sequential administration of amyl nitrate, sodium nitrite, and sodium thiosulfate. However, the FDA has approved intravenous hydroxocobalamin for treatment of cyanide exposure. The initial dose is 5 g and can be repeated if necessary.[38]

Pulmonary Agents (Phosgene and Chlorine)

Pulmonary or choking agents cause an inflammatory reaction when they come into direct contact with the eyes and upper airway. They can be life-threatening if inhaled. No specific antidote exists. Treatment is mainly supportive and consists of removal of the patient from the source, decontamination, airway maintenance, bronchodilator administration, and eye irrigation.

KEY CONCEPTS

- Emergency department preparedness for a radiation incident must address decontamination (an external freestanding decontamination unit is best), triage, staff safety, PPE, and diagnostic procedures that emphasize radiation monitoring. The emergency personnel should make sure that they know their radiation safety officer.
- Management of acute life-threatening conditions takes priority over radiation-associated issues.
- Aerosol dispersal is a likely route that terrorists may use to deploy biologic weapons, so victims will present primarily with respiratory complaints.
- In addition to "flulike" symptoms, anthrax typically causes mediastinal widening, pulmonary consolidation, and pleural effusions best seen on chest computed tomography scans.
- Smallpox can spread in a hospital environment; thus patients thought to have smallpox should be admitted to locations separated from the rest of the hospital.
- Decontamination is a key activity in the management of patients exposed to chemical agents, and hospitals should provide this intervention.
- Nerve agents are organophosphates, and patients exposed to these agents are treated with large doses of atropine (repeated frequently), pralidoxime, and benzodiazepines.

Chapter 195

Observation Medicine and Clinical Decision Units

Malcolm Mahadevan and Louis Graff IV

PRINCIPLES OF OBSERVATION MEDICINE

Observation services are an extension of emergency department (ED) services specifically designed to address unmet patient needs. Observation services improve patient care by continuing the evaluation and management of selected ED patients who would otherwise require admission for acute care services. Approximately 80% of patients treated on observation services can be sent home without the need for hospitalization. The cost to evaluate and to treat these patients is half that incurred by admission.[1,2] In addition, the physician threshold for extended evaluation (traditionally provided with hospitalization) is lowered. Patients with atypical signs and symptoms are more fully evaluated to rule out serious conditions, such as acute myocardial infarction or acute appendicitis. Thus in addition to lower costs, there is also a simultaneous decrease in the inadvertent release home of patients with serious disease.[1]

An ED observation unit is a designated area to provide these short-term services for up to 24 hours. Names given to observation units vary and include *chest pain unit, clinical decision unit,* and *rapid diagnostic treatment unit*. An ED-based observation unit is not a holding unit. A holding unit stems from hospital overcrowding and is an area where patients admitted to the hospital are held passively until they can be transferred to an inpatient hospital bed.

Two categories of patients benefit from extension of the usual 2- to 4-hour ED visit to up to 24 hours. One group is selected patients with a critical diagnostic syndrome (Box 195-1). These are patients whose diagnoses are unclear after the initial ED evaluation and who will benefit from further evaluation during observation. They are either admitted if they are found to have a serious disease or released home. The second group is patients with selected emergency conditions (see Box 195-1). Those patients not successfully treated during the traditional ED treatment period benefit from further treatment in an observation unit.

OBSERVATIONAL APPROACH

The traditional ED encounter lasts less than 4 hours. The physician performs a history and physical examination and orders laboratory and radiologic tests. When the test results return, the physician either admits the patient to the hospital or discharges the patient home.

The observational approach adds a third option at the completion of the initial evaluation. The patient is treated and further tested for up to 24 hours. After the observation period, patients are then admitted to the hospital or discharged home.

Observation begins with the physician's writing of observation orders. The patient is transferred to the observation unit from the main ED. An observation unit chart is generated, and treatment and investigations are begun. The observation orders include the clinical impression, the reason for observation, the therapeutic evaluation plan, the expected outcome, the criteria and time frame for disposition, and the physician responsible for the patient's care and disposition. The responsible physician may be the emergency physician or the patient's private physician or a consultant.

Adequate staffing of the observation unit is crucial for the success of the program. The patient receives services for an average of 12 to 24 hours beyond the ED visit. The amount of nursing staff required is proportional to the type and intensity of treatment offered, the number of beds, whether the beds are monitored or nonmonitored, and the patient's acuity. The average staff is one registered nurse per four to six patients in monitored beds and one registered nurse per six to nine patients in nonmonitored beds.

Staff nursing skills should be broad based and include the ability to care for patients of all ages with a wide spectrum of conditions. Nurses should have the ability to provide critical care when it is needed and frequent assessments of patients under their care. Nurses should be able to provide prolonged patient and family interactions, including hygiene care, meals, and emotional support. These are all skills present in emergency nurses. When nonemergency nurses are recruited for the observation unit, they should be cross-trained, serving some shifts each month in the ED.

Additional physician staffing is also required for the observation unit. Management of ED patients in the observation unit for an additional 12 to 14 hours requires approximately a doubling of the physician service for a single patient.[3] Calculations of the physician staffing for the amount of additional services will be approximately one full-time equivalent for every 2000 patients observed per year. As with the nurses, physicians in the observation unit must have broad-based knowledge and experience in the management of a wide variety of disease processes. Emergency physicians possess the skill sets necessary for observation medicine. The emergency physician is ultimately responsible for the care of the patient and needs to provide clear leadership at all times.

Patients and staff involved in the observation process must be well informed about the goals and benefits provided by the extended service. Well-written, condition-specific observation protocols ensure a continuum of care, including the transfer of patient care at shift change. The services provided in an ED observation unit are equivalent to inpatient services, albeit at an accelerated pace.

Box 195-1 Conditions Appropriate for Observation

Evaluation: Critical Diagnostic Syndromes
- Abdominal pain
- Chest pain
- Deep venous thrombosis
- Gastrointestinal bleeding
- Syncope
- Transient ischemic attack
- Trauma
  - Blunt abdominal
  - Blunt chest
  - Penetrating abdominal
  - Penetrating chest
  - Head injury

Treatment: Emergency Conditions
- Asthma
- Atrial fibrillation
- Congestive heart failure
- Dehydration
- Infections
  - Pneumonia
  - Pyelonephritis

Box 195-2 Observation Criteria for Abdominal Pain*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)
- Severe dehydration
- Hemodynamic instability
- Sodium concentration < 120 mEq or > 155 mEq
- Concomitant acute severe medical condition (e.g., acute renal failure or sepsis)
- Acute peritonitis
- Probability of discharge within 24 hours < 80%
- High or moderate probability of serious, dangerous disease, such as acute appendicitis, small bowel obstruction, or bowel perforation

Inclusions (appropriate to refer to observation if at least one criterion is met)
- Inability to correct symptoms
- Inability to take fluids orally
- Possibility that patient has serious, dangerous cause of symptoms
- Inability to control pain with oral medication

*Note: These criteria are based on the authors' expert opinion.

Consultants must be available to the observation unit as they would be to any inpatient service. They provide therapeutic and management advice and assist in the serial examinations of patients as requested. The observation unit must identify needs, notify the consultant, assemble all the needed information, and carry out the consultant's recommendations within the shortest time frame possible.

Residents and medical students are included in the functioning of the observation unit because exposure to the observational approach is an integral part of their training program. Emergency residents specifically need training in this area of emergency medicine through clinical practice, lectures, and review of published literature. Residents from other specialties benefit from the exposure by having a better understanding of the role of observation medicine and its applicability in a select group of ED patients.

The amount and type of ancillary personnel needed in the observation unit depend on its size and the type of services offered in the unit. An observation unit that offers chest pain evaluation may require different ancillary personnel than one that does not. Personnel may be from outside the department or function full-time in the observation unit (e.g., respiratory therapists). They may also be personnel who have not traditionally been available to the ED, such as psychiatric nurses. Also crucial for proper functioning of the unit are adequate secretarial and clerical staff.

The structure of the observation unit will determine its clinical effectiveness and financial viability. Models for the structure of the observation unit are reviewed in the American College of Emergency Physicians textbook *Emergency Department Design.*[4] An observation unit that is properly designed and located adjacent to the ED will result in a 50% lowered cost compared with traditional hospital admission while providing equivalent or improved quality of patient care.

An emergency physician designated and empowered to manage the observation unit is critical for success. The complexity of patient care is multiplied when an ED adds observation services. The manager develops and implements clinical protocols for efficient quality patient care. The manager schedules and supervises the observation unit staff and leads the continuous quality improvement team monitoring the observation unit's functioning.

CLINICAL CONDITIONS

Evaluation of Critical Diagnostic Syndromes

Abdominal Pain

Traditional Approach. Abdominal pain is one of the most frequent complaints in the ED and accounts for 4 to 8% of all visits.[5] The typical ED evaluation of the patient with abdominal pain includes a thorough history and physical examination and the appropriate diagnostic tests. Within the short time frame of 2 to 4 hours, patients are given a provisional diagnosis and are either hospitalized or sent home.

Problem with Traditional Approach. The ED evaluation is inadequate for many patients, and in 40% of patients the origin of abdominal pain is never determined. Acute appendicitis is the most common abdominal surgical emergency and illustrates the inadequacies of the traditional approach. The diagnosis of acute appendicitis is missed in 20 to 30% of cases (false-negative decisions). In addition, 20 to 30% of patients taken to surgery for acute appendicitis are found to have no abnormality (false-positive decisions).[5] Whereas abdominal computed tomography (CT) imaging has been found to improve physician performance in identifying patients with acute appendicitis,[6-8] there is increasing concern for the amount of ionizing radiation exposure to patients from the increased use of CT.[9]

Observational Approach. With observation, the ED evaluation can be extended from 2 to 4 hours to up to 23 hours for selected patients (Box 195-2). After the initial history and physical examination of the patient, the physician estimates the probability that the patient has appendicitis by use of validated risk stratification tools, such as the Alvarado score. Those patients deemed to have a low probability of disease are ideal candidates for the observational approach.[10] Patients who are at greater risk of having their diagnosis missed, such as those who are immunocompromised, pregnant, or at the extremes of age, often benefit from observation. Elders in particular benefit from observation; surgical problems are often missed because of the atypical clinical findings that occur with older age.[11]

During the period of observation, the patient is usually kept fasted and hydrated intravenously. Serial abdominal examinations

www.ketabpezeshki.com 66485457-66963820

are repeated at 4-hour intervals, and laboratory tests such as complete blood count and C-reactive protein level are repeated as appropriate. Imaging and consultations are also arranged during this time frame. Patients without appendicitis will experience improvement of their pain and have had completion of diagnostic workup and exclusion of surgical disease.[12] Patients are hospitalized if they have no improvement, worsening of their clinical findings, or surgical disease diagnosed by testing. In patients who do have appendicitis, signs and symptoms will continue or worsen.[13]

Physician decision-making improves with observation, and false-positive surgeries can nearly be eliminated. Intensive observation with serial physical examinations at least every 8 hours rather than once per day has been found to reduce the false-positive rate from 20 to 5%.[13,14] The use of a period of observation can also help identify many patients whose diagnoses otherwise would be missed during the initial ED evaluation. Initially, many appendicitis patients have few clinical signs or symptoms of appendicitis on presentation, making diagnosis difficult.[12] Physicians delaying disposition decisions in questionable cases can avoid these false-negative decisions. Appendicitis patients have more signs and symptoms during short-term observation, whereas those without the disorder clear their signs and symptoms. Thus fewer patients have an unclear clinical picture after observation with fewer false-negative decisions.[15] Missing of the diagnosis at the initial evaluation delays surgery up to 72 hours and doubles complications (perforation, abscess).[11] Physicians who observe selected patients with low probability of disease rather than discharge them after their initial evaluation can avoid most of these missed diagnoses and the resulting complications.

Chest Pain

Traditional Approach. The ED evaluation of chest pain is composed of two assessments: (1) the probability that the patient has an acute myocardial infarction (AMI) or acute coronary ischemia (ACI) and (2) the risk of the patient's having a life-threatening event. These two factors determine the appropriate setting for further testing and monitoring. The probability of AMI is traditionally assessed in the ED with a directed history, physical examination, and electrocardiogram (ECG) and an initial measurement of cardiac biomarkers, such as creatine kinase MB fraction (CK-MB), cardiac troponin I or T, B-type natriuretic peptide (BNP), and myoglobin. Other markers, such as high-sensitivity C-reactive protein, myeloperoxidase, and D-dimer, are used less frequently.[1-5,7,8,16-23]

Patients with clear evidence of AMI on the ECG are potential candidates for immediate reperfusion therapy with either thrombolytics or emergency angioplasty. This subset is at high risk for life-threatening events and best managed in the coronary care setting with close monitoring. This approach has been shown to improve survival in patients with AMI.

Depending on the evaluating physician's threshold, chest pain patients without definite evidence of AMI at initial evaluation are generally admitted to the hospital to confirm or to exclude ("rule in" or "rule out") ACI or AMI. Patients who are judged to have low probability of ACI after the initial evaluation are released home for outpatient follow-up.

Problem with Traditional Approach. The poor performance of initial diagnostic testing makes the evaluation of chest pain highly dependent on clinical judgment. The initial ECG is diagnostic in only 50% of AMI patients,[24] and the initial CK-MB measurement has a sensitivity of only 35%.[25] Reliance on physician judgment and initial ED testing has resulted in as many as 2 to 5% of AMI patients being discharged home with inadvertent reassurance.[1,26] AMI patients not identified at the initial evaluation and released from the ED have up to a 25% risk of poor outcome.[1] Fear of inadvertently releasing AMI patients has led many emergency physicians to err on the side of admitting a large number of patients who do not have AMI or unstable angina. As a result of the increased sensitivity of a more liberal admission policy, two thirds of patients admitted for chest pain have a noncardiac cause of their symptoms.[1] Costs range in the billions of dollars for these negative evaluation hospitalizations.[4] Despite this liberal admission policy, missed AMI remains one of the leading causes of malpractice suits against emergency physicians.[27]

Box 195-3 Observation Criteria for Chest Pain*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)
- Diagnostic electrocardiographic changes or positive cardiac biomarkers
- Moderate or high probability of serious, dangerous disease or risk of adverse event
- Continuing chest pain
- Unstable vital signs

Inclusions (appropriate to refer to observation if all criteria are met)
- Nontraumatic chest pain
- Low probability of serious, dangerous disease or risk of adverse event
- Stable vital signs

*Note: These criteria are based on the authors' expert opinion.

Observational Approach. The emergency physician can use the observation unit to extend the evaluation of selected patients with chest pain (Box 195-3). When it is used principally for such a purpose, the observation unit has been termed a chest pain unit. The chest pain unit has been successful in improving the sensitivity and specificity of the evaluation process.[28,29] Patients with low risk of AMI are transferred to the observation unit. Patients unsuitable for observation unit evaluation include those who have a high to moderate probability of acute myocardial ischemia, unstable vital signs, electrocardiographic findings of AMI, or persistent or recurring chest pain consistent with unstable angina.

The physician identifies patients with low probability for ACI by use of one or more risk stratification tools. Risk stratification based on classic risk factors alone has been shown to be a poor predictor of short-term outcome.[30] Risk stratification based on electrocardiographic findings is more reliable. The Brush ECG criteria classify as low risk those without ST segment elevation or depression, T wave inversion or strain, new (or presumed new) Q waves, left bundle branch block, or paced rhythm.[31] Another useful risk stratification tool is the Goldman protocol, which uses history, physical examination, and electrocardiographic findings to classify patients into high (>70%), moderate, or low (>7%) risk.[32] Another tool is the acute cardiac ischemia time-insensitive predictive instrument, which uses age and gender of the patient, presence or absence of chest pain, and electrocardiographic findings to assign a probability of acute ischemia.[33]

Patients admitted to the observation unit are first evaluated to rule out a myocardial infarction. They are serially tested with cardiac markers and ECGs. CK-MB estimation at 0, 3, and 6 hours after presentation has 100% sensitivity, 98% specificity, and 100% negative predictive value in the detection of AMI.[28,29] Other useful serum cardiac markers are the troponins (I and T) and myoglobin. Patients who present more than 24 hours after symptom onset have negative CK-MB and myoglobin testing findings, but troponin T or I remains positive for up to 6 days. Patients are monitored with continuous ECG monitors equipped with dysrhythmia alarms and memory storage capabilities. Continuous electrocardiographic ST segment monitoring can detect

www.ketabpezeshki.com 66485457-66963820

dynamic ST segment changes indicative of ischemia, which, when present, indicate an increased likelihood for an adverse cardiac event.[34] Continuous electrocardiographic monitoring also helps detect arrhythmias that may be associated with acute coronary syndrome.

After evaluation to exclude AMI, the patient is evaluated for possible acute coronary syndrome. This may be performed before release of the patient from the observation unit or at follow-up evaluation within 72 hours of discharge. The most common testing modality used is exercise stress testing.[35] Patients who obtain their target heart rate without electrocardiographic evidence of ischemia can be released home. They have an annual mortality rate of less than 1%.[35] The performance of exercise testing depends on the ability of the patient to exercise adequately, gender (women have higher false-positive rates), interpretability of the resting ECG, and availability of the test. Other testing modalities include stress echocardiography, technetium (^{99m}Tc) sestamibi scanning, and cardiac CT angiography.

Approximately one third of ED patients with chest pain are candidates for observation, with 80 to 85% released home after observation.[1] This reduces the hospitalization rate from 60 to 70% down to 40 to 50%.[1] The cost of evaluation with observation is half that of traditional evaluation with hospitalization.[1] The safety and cost-effectiveness of the observation approach have been confirmed in four randomized clinical trials.[36-39] Payers expect clinicians to be cost-effective and to use observation for evaluation of patients with chest pain when it is appropriate. The Centers for Medicaid and Medicare Services began audits in 2010 by Recovery Audit Contractors to deny payment for patients with low probability of AMI chest pain who were admitted to the hospital rather than evaluated in the lower cost outpatient observation unit. The use of observation units for chest pain evaluation is thus becoming the standard in U.S. hospitals.

Deep Venous Thrombosis

Traditional Approach. The primary objectives for the treatment of deep venous thrombosis (DVT) are to prevent pulmonary embolism, to reduce morbidity, and to prevent or to minimize the risk for development of postphlebitic syndrome. Patients with suspected DVT are usually hospitalized when diagnostic testing is unavailable in the ED or the diagnosis has been confirmed and further management is required. Traditionally, anticoagulation with unfractionated heparin has been administered by continuous intravenous infusion for 5 to 7 days while oral anticoagulation is instituted.[40] Meta-analyses of randomized trials of unfractionated heparin and low-molecular-weight heparin (LMWH) showed that they were similar, with a risk of recurrent DVT of 4%, a risk of pulmonary embolism of 2%, and a risk of major bleeding of 3%.[41,42] The anticoagulant response to this treatment varies markedly among patients, and therefore the dosage must be monitored by coagulation profiles.[43]

Problem with Traditional Approach. New modalities for investigation and treatment have made it possible to manage DVT on an outpatient basis with lower costs than with hospitalization. There are new, less invasive investigative tests and newer therapeutic agents that do not require monitoring of coagulation profiles.

Observational Approach. The role of the observation unit in the management of patients thought to have DVT is for diagnostic testing as well as for initiation of therapy with LMWH and patient education. Patients often present during the night or on weekends when definitive tests for DVT (e.g., Doppler ultrasonography) are not available. The patient may have a positive D-dimer test finding, which requires a confirmatory definitive test because of its poor specificity.[44] In these circumstances, the patient can be anticoagulated for the short term with one dose of LMWH (enoxaparin, 1 mg/kg twice daily) until the diagnosis can be clarified. If the diagnosis is confirmed, the patient can be admitted or treated as an outpatient on the basis of hospital protocol. Patients considered for outpatient management are instructed in how to administer the medication. They are educated about DVT and its complications and the possible side effects of the LMWH. Appropriate follow-up evaluation is also arranged before discharge. With this approach, patients spend 67% less time in the hospital and have greater physical activity and social functioning than their standard heparin cohorts do.[45] Outpatient management is not recommended if the patient has proven or suspected concomitant pulmonary embolism, significant comorbidities, extensive iliofemoral DVT, active bleeding, renal failure, or poor follow-up compliance. LMWH is administered by subcutaneous injection in doses adjusted for the patient's weight, without laboratory monitoring.

Outpatient testing with venous compression ultrasonography has become readily available.[46] It is both sensitive and specific for the diagnosis of proximal (femoropopliteal) DVT.[47] When repeated compression ultrasonography is compared with impedance plethysmography, compression ultrasonography is superior in detection of DVT.[46] It has been proved to be a safe method of deciding when to administer anticoagulation.[44] The D-dimer assay has also been shown to be a useful adjunct to compression ultrasonography in outpatient testing.

Upper Gastrointestinal Bleeding

Traditional Approach. Most patients with upper gastrointestinal bleeding are admitted to the hospital after initial ED assessment and stabilization.

Problem with Traditional Approach. Upper gastrointestinal bleeding is a common and potentially life-threatening condition with an overall mortality rate of 6 to 10%.[48] However, most cases of upper gastrointestinal bleeding are self-limited, and 80% of patients have only one bleeding episode.[49]

Observational Approach. Not all patients with upper gastrointestinal bleeding do poorly, suggesting that outpatient management is possible if patients at high risk for further bleeding can be identified. Prognostic indicators include the patient's age, heart rate, systolic blood pressure, orthostatic changes in blood pressure or pulse, color of stool or emesis, anticoagulant use, and comorbid conditions.[50] In an attempt to refine diagnostic accuracy, risk assessment, and disposition, several scoring systems have been developed. Some practitioners use hemodynamic stability, intensity of bleeding, and underlying health status as predictors of rebleeding, need for surgery, and mortality.[51] Some use a period of observation with early endoscopy to identify the patient who can be discharged early. Patients found to have clean-based ulcers at endoscopy have a rebleeding rate of less than 2% and virtually never require urgent intervention for recurrent bleeding and can be released. Use of this approach has been proved to be both safe and cost-effective; a prospective clinical trial demonstrated that 24% of patients can avoid hospitalization, with cost savings of $990 per patient.[52]

Syncope

Traditional Approach. Syncope is caused by a spectrum of disease entities. ED evaluation includes a thorough history, physical examination, and 12-lead ECG. Patients with evidence of possible myocardial ischemia or a cardiac cause of their syncope are usually admitted to the hospital because cardiac syncope has a high risk of death (up to one third will have a poor outcome).[53] Those with concomitant heart failure have a 25% mortality rate at 30 days.[54] On the other hand, patients with noncardiac syncope have a low risk of adverse events (1%) and can be managed as outpatients.[53]

www.ketabpezeshki.com 66485457-66963820

BOX 195-4 Observation Criteria for Syncope*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)

History of dyspnea or loss of consciousness > 10 minutes or trauma or seizure
Past history of congestive heart failure, chronic obstructive pulmonary disease, structural heart disease, or ventricular dysrhythmia
Abnormal hematocrit level < 30%, elevated B-type natriuretic peptide or pro-B–type natriuretic peptide level, positive cardiac biomarkers, or abnormal electrolyte values
Evidence of injury or ischemia on electrocardiography or documented or highly suspected unstable dysrhythmia
Low oxygen saturation or unstable vital signs
Stool positive for blood
New focal neurologic findings or persistently altered mental status
High or moderate probability of serious, dangerous disease or adverse event

Inclusions (appropriate to refer to observation if any criterion is met)

Possibility of pathologic cause of the syncope
Low probability of serious, dangerous disease or adverse event

*Note: These criteria are based on the authors' expert opinion.

Problem with Traditional Approach. Attempts to exclude a possible cardiac cause of syncope usually result in 25 to 40% of patients being hospitalized for further evaluation and management.[54] The traditional ED evaluation identifies only 50% of patients with a serious cause of their syncope,[55] and this has often resulted in a liberal admission policy; however, one study found that only 12% of patients had a serious cause of syncope that justified hospitalization.[56] It is estimated that a third of patients admitted after their ED evaluation have very low risk of an adverse event (<2%) and would be appropriate for outpatient observation evaluation.[57]

Observational Approach. The use of observation for selected patients with syncope reduces unnecessary hospitalizations (Box 195-4). Patients with a cardiac syncope have a poor prognosis and need to be identified. These patients often do not have chest pain as a symptom, but they may have ischemic changes on the ECG, arm or shoulder pain, or prior history of exercise-induced angina. A "rule out myocardial infarction" evaluation with cardiac monitoring, serial ECGs, and enzyme measurement may be the only way to identify these patients. Prolonged electrocardiographic monitoring can point to a specific cause in up to one fifth of patients, with half of all abnormalities detected in the first 24 hours.[58]

The challenge for the emergency physician is to risk stratify patients into very low risk, who can be discharged home; low risk, who are appropriate for outpatient observation; and moderate to high risk, who are appropriate for acute care hospitalization. Many factors have been found to correlate with adverse outcomes and should be considered by the clinician in the risk stratification, but attempts to create simple high-reliability decision rules have not been successful.[59] Martin found that the 1-year risk of dysrhythmia or death in syncope patients correlates with four factors: an abnormal ECG, history of ventricular dysrhythmia, history of heart failure, and age older than 45 years.[59] Patients with none of these risk factors have only a 4.4% rate of adverse events at 1 year and may be appropriate for outpatient evaluation. In contrast, patients with three or four risk factors have a 58% adverse outcome rate and should be hospitalized. Patients with one or two risk factors have intermediate risk and may be appropriate for evaluation on an observation service. The San Francisco Syncope Rule has been found to have sensitivity in identifying patients who are at immediate risk for serious outcomes within 7 days that ranges in different studies from 74 to 96%.[60,61] Its criteria are abnormal electrocardiographic findings, history of congestive heart failure (CHF), dyspnea, hematocrit level of less than 30%, and hypotension.[60,61] The Risk stratification Of Syncope in the Emergency department (ROSE) criteria suggest that an elevated BNP level, Hemoccult-positive stool, anemia, low oxygen saturation, and presence of Q waves on the ECG predict serious outcomes at 30 days.[62] These rules had a sensitivity of 87% and a negative predictive value of 98.5% to help risk stratify patients. In this study, the isolated finding of a BNP level above 300 pg/mL was a major predictor of serious outcomes and was present in 89% of patients who died within 30 days. Another study found that 6.1% of patients had severe outcomes within 10 days of syncope evaluation.[63] The mortality rate was 0.7%, and 5.4% of patients were readmitted or experienced major therapeutic intervention. Risk factors associated with severe short-term outcomes included abnormal ECG, history of CHF, age older than 65 years, male gender, history of chronic obstructive pulmonary disease, structural heart disease, presence of trauma, and lack of prodromal symptoms. The Evaluation of Guidelines in SYncope Study 2 (EGSYS 2) prospectively observed nearly 400 patients at 1 month and 2 years. The death rate was 2% at 1 month and 9% at 2 years. Patients with advancing age, presence of structural heart disease, or abnormal ECG had higher risk.[64] Osservatorio Epidemiologico sulla Sincope nel Lazio (OESIL) score is another clinical decision rule that has been found to have limited accuracy.[65,66] Additional factors indicating that a patient should be admitted rather than placed in outpatient observation are abnormal neurologic findings, positive cardiac biomarkers, and loss of consciousness for longer than 15 minutes.

Because many factors should be considered in the risk stratification for patient disposition to observation or hospitalization (see Box 195-4), the best practice approach is to develop an institutional consensus on this risk stratification and to codify it in a syncope order set. This approach reduces physician variability in decision-making by more uniformly adopting evidence-based practices, which improves both quality of patient care and use of health care resources.

During the observation period, serial examination of patients is carried out, including vital signs, with the majority of patients safely discharged home without hospitalization.[67] Continuous electrocardiographic monitoring, consultation, serial cardiac enzyme determinations, and further tests, such as two-dimensional echography of the heart, psychiatric assessment, and tilt table testing, should be arranged when appropriate. Tilt table testing is a useful investigation in patients with recurrent syncope when heart disease is not suspected. Up to 60% of patients who have vagally mediated syncope can be detected by this modality.[68] The period of observation can also identify patients with cardiac dysrhythmias or sinus pauses who are candidates for more extensive diagnostic evaluation in the hospital.

Transient Ischemic Attack

Traditional Approach. More than 300,000 people suffer a transient ischemic attack (TIA) each year.[69] For most patients, it is a transient event that will not recur if they take an aspirin each day. However, for 10% of patients, it is a warning sign that they will suffer a stroke unless they are appropriately evaluated and treated.[70] Traditionally, the patient is assessed in the ED with history, physical examination, laboratory tests, electrocardiography, and head CT scan. Most patients are then hospitalized for serial clinical evaluations, neurology consultation, carotid Doppler testing, echocardiography, and cardiac monitoring.[67]

www.ketabpezeshki.com 66485457-66963820

Problem with Traditional Approach. The problem with the traditional approach is that most TIA patients are admitted to the hospital. After 3 days of evaluation, few will be found to have carotid or heart disease requiring an intervention.

Observational Approach. Observation is an alternative to hospitalization for TIA patients with a normal ED evaluation for whom the emergency physician still has concern. An accelerated diagnostic observation protocol was compared with acute care hospitalization in a prospective randomized clinical trial. All patients had full evaluation in the observation unit or inpatient ward with serial clinical examinations, neurology consultation, carotid duplex ultrasonography, echocardiography, and cardiac monitoring.[71,72] Clinical outcomes were equivalent with the two approaches, but the observation unit was more efficient (length of stay, 25 hours vs. 61 hours) and had lower costs ($890 vs. $1547).[71,72]

Trauma

There are more than 30 million trauma-related ED visits annually.[73] Patients with serious injuries require hospitalization for definitive therapy, whereas those with minor injuries can be discharged home after treatment. The problem with the traditional ED approach is that many patients have injury patterns or actual injuries that fall somewhere between these two scenarios. If these patients are released, there is a risk that some will have poor outcomes as a result of missed injuries. On the other hand, because the majority of these patients do not have serious injuries, admitting this group to the hospital will result in a waste of scarce health care resources.

Observation units have been found to be an efficient and useful strategy in the evaluation and management of trauma victims.[74] With observation, selected patients can be evaluated further to determine the need for admission. One study of 20,000 patients treated in an ED observation unit during a 12-month period found that 3% of patients were admitted to the observation unit, with 86% safely discharged home without the need for admission.[74]

Blunt Abdominal Injury

Traditional Approach. Current ED management of blunt abdominal trauma (BAT) includes history, physical examination, blood analysis, plain radiography, ultrasonography, and CT scan. After initial stabilization and exclusion of other major injuries in the ED, most patients suffering BAT are admitted to the hospital for further evaluation and monitoring.

Problem with Traditional Approach. The initial evaluation is inadequate for accurate disposition of many BAT patients. One third of patients who do not have any symptoms or signs suggestive of intra-abdominal injury may actually have significant injury.[75] Also, because none of the present modalities for investigation of the presence of injury is 100% sensitive, many patients with initially normal investigations are hospitalized.

Observational Approach. BAT patients appropriate for observation include those who, after initial evaluation, have no clear evidence of serious injury on physical examination but remain at risk for serious injury because of the mechanism of the injury or the individual's personal health (e.g., advanced age or use of anticoagulants). Evaluations during observation for up to 23 hours include repeated physical examinations, laboratory testing, imaging, and specialty consultations. Patients are hospitalized if their condition deteriorates during the observation period or if, after testing, they are found to have serious internal injury. Patients with normal findings on evaluation and the ability to tolerate feeding can be safely released home. Patients who have sustained significant BAT by mechanism of injury or have equivocal findings on abdominal examination should undergo further testing, such as CT scan, for detection of occult injury.[76] Ultrasonography (focused assessment with sonography for trauma [FAST]) is being increasingly used in the initial evaluation of the patient with BAT because it is a rapid noninvasive study with 99% specificity for detection of abdominal injury.[77] However, it cannot be used to rule out serious intra-abdominal injury because a meta-analysis of 62 trials found the overall sensitivity of FAST to be only 79%.[77] CT alone is not adequate to rule out serious injury, with sensitivity of only 80 to 95%.[78] Short-term observation alone in patients with BAT is not sufficient because up to 20% of patients with significant injury will not have abdominal tenderness or develop it even after a short period of observation.[78] Thus the prudent approach to patients with significant BAT without clear evidence of intra-abdominal injury is the use of a diagnostic test, such as CT, together with a period of observation.

Penetrating Abdominal Injury

Traditional Approach. Most patients with penetrating abdominal injury are hospitalized for further evaluation, which may include wound exploration in the operating room and additional diagnostic testing.

Problem with Traditional Approach. Many of these hospitalizations are unnecessary because only two thirds of patients with abdominal stab wounds have a breach of the peritoneum, and two thirds of these do not sustain visceral injury.[79]

Observational Approach. A period of observation can identify those patients who do not require surgical intervention. Patients undergo serial examinations by the physician, further diagnostic testing, and specialty consultation. Those without evidence of peritoneal perforation or visceral injury after evaluation are sent home after proper wound care.

The conservative approach to penetrating abdominal wounds was developed in the 1970s. Those without peritoneal breach can be safely sent home after wound care and a period of observation without the need for hospitalization. Those with stab wounds to the abdomen with peritoneal breach but a negative finding on diagnostic laparoscopy or imaging with CT scan or ultrasonography can be safely managed in an observation unit.[79-82] Patients with significant intra-abdominal injuries identified during observation are admitted; the 70 to 90% of patients without such injuries are released home.[80,83] Gunshot wounds are often more difficult to evaluate than stab wounds. However, patients who appear to have tangential gunshot wounds can avoid surgery with observation if they are hemodynamically stable and have initial negative test findings. Penetrating wounds are manifested differently in children than in adults.[84] Initial diagnostic testing with CT and diagnostic peritoneal lavage in children detects only 50% of injuries, with only 30% of patients having localized tenderness. Observation can help avoid unnecessary surgery in patients without injury and missing of the diagnosis in those without clear evidence of injury.

Blunt Chest Trauma

Traditional Approach. Many patients who have a history of blunt chest trauma (BCT) in high-velocity accidents are admitted to the hospital to rule out myocardial or pulmonary contusion.

Problem with Traditional Approach. Very few patients admitted to the hospital with BCT from high-velocity accidents without initial evidence of injury are found to have serious injury during hospital evaluation.[85]

Observational Approach. Patients with isolated BCT who are otherwise stable with a normal ECG are suitable for a period of observation to exclude myocardial injury. During the period of observation, patients are monitored with continuous

www.ketabpezeshki.com 66485457-66963820

electrocardiography, specifically assessing for dysrhythmias. Serial enzyme determinations, such as troponin level, are also carried out to detect evidence of myocardial injury. Those patients with sternal fractures or other evidence of higher risk of intrathoracic injury should be considered for transesophageal echocardiography.[86] Those with normal evaluations during the period of observation are released home for outpatient follow-up.

Much of the period of observation in patients with BCT focuses on identification of the presence and prognosis of myocardial contusions. The overall incidence of cardiac-related complications in these patients is low (0.1%).[87] Patients with blunt cardiac trauma who have complications usually have an abnormal ECG or abnormal CK-MB or troponin level at presentation. Conversely, a normal ECG and CK-MB and troponin levels correlate with the lack of clinically significant complications.[88,89] Patients who have isolated chest wall contusions and no abnormality of serial CK-MB or troponin values and no electrocardiographic abnormalities or dysrhythmia during 6 to 12 hours of electrocardiographic monitoring are unlikely to have complications.

Penetrating Chest Injury

Traditional Approach. Patients with penetrating chest injury present with a spectrum of severity ranging from severe life-threatening injury requiring urgent operative intervention to hemodynamically stable patients with a normal initial evaluation. Most patients presenting with penetrating chest injuries are admitted to the hospital. Often, even those with a normal initial evaluation are admitted for exclusion of serious injury to the heart, lungs, and major blood vessels.

Problem with Traditional Approach. The accuracy of this approach is limited because many patients with evidence of injury are admitted but have no further deterioration or need for medical therapy. On the other hand, there are those without obvious evidence of serious injury who will have a negative outcome if they are released after the initial evaluation.

Observational Approach. A period of observation combined with diagnostic imaging can improve clinical decision-making. Patients with evidence of a small pneumothorax or hemothorax can be monitored for deterioration. Those without evidence of serious injury but of concern to the physician can likewise be observed for complications. During the period of observation, patients are monitored for respiratory or hemodynamic compromise. Repeated chest radiographs can detect the development of hemothorax or pneumothorax. Patients who deteriorate during the period of observation require hospitalization.

The safety and efficacy of managing asymptomatic stab wound victims in the short-term observation unit have been clearly established in multiple studies.[90-92] A total of 5 to 15% will require hospitalization because of development of delayed pneumothorax, subcutaneous emphysema, hematemesis, or pneumopericardium.[90] In addition, the majority of stab wound victims with small pneumothoraces or hemothoraces will be treated solely with a chest tube without further surgical intervention. Major trauma centers can manage many of these patients as outpatients without hospitalization after a period of observation.

Patients with penetrating wounds to the cardiac area of the chest (between the nipples), the region of the great vessels, or the thoracoabdominal area usually require more intensive testing to exclude injury not only to the heart, major vessels, and lungs but also to the diaphragm and the abdominal organs. Echocardiography may detect pericardial fluid or tamponade in patients with penetrating injury close to the heart.[93-95] Patients with small effusions may be observed in a monitored setting with serial examinations, whereas patients with large effusions should be treated surgically.[95] Patients with normal findings on echocardiography can be observed in the observation unit. Even patients with small effusions may have sustained a serious injury, so the intensity of monitoring needs to be high.

Treatment of Emergency Conditions

Asthma

Traditional Approach. More than 20 million people in the United States are afflicted with asthma. Acute exacerbation of asthma is a common ED presentation, with estimated annual admissions exceeding 450,000.[96] Traditionally, therapy is provided in the ED for 2 to 4 hours, consistent with national guidelines.[97] Initial assessment includes history, physical examination, oxygen saturation, and peak expiratory flow rate (PEFR) or forced expiratory volume in 1 minute. Treatment consists of beta-agonists, magnesium sulfate, and steroids, when appropriate. Patients who do not improve after 3 or 4 hours of treatment are hospitalized for further management.

Problems with Traditional Approach. With this approach, one third of patients are hospitalized.[98] This translates into an estimated medical cost of $1.2 billion annually.[98,99] Another pitfall in the traditional ED treatment of asthma is that short encounter times do not allow identification and aggressive treatment of patients with a higher tendency for relapse. This leads to repeated ED visits, additional medical costs, and diminished quality of life.

Observational Approach. An alternative to hospitalization for patients failing to respond to ED treatment is the use of an extended, short-term intensive protocol for 8 to 12 hours in an observation unit for selected patients (Box 195-5).[2] With extended treatment, 80% of such patients can be discharged home.[2] Inclusion criteria for observation unit management are failure of standard initial management and continued respiratory distress. Increased risk of relapse is indicated by a history of numerous asthma-related ED or clinic visits within the past year, use of more outpatient medications (including home nebulizers), and longer duration of symptoms.[98] Exclusion criteria for observation include unstable vital signs, evidence of impending respiratory failure ($Paco_2 > 45$ mm Hg, $Pao_2 < 55$ mm Hg), and severe airway restriction (PEFR < 80 L/min after first inhaled beta-agonist treatment). Also considered during selection for observation are factors that correlate with unsuccessful treatment during observation. These

Box 195-5 Observation Criteria for Asthma*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)
- Respiratory fatigue or failure (respiratory rate > 40, oximetry < 90%, $Pco_2 > 45$, pH < 7.3)
- Inability to perform spirometry or peak flows
- Peak flow after third beta-agonist < 30% of predicted
- Concomitant illness (e.g., pneumonia, heart failure)
- Bronchospasm due to aspiration or foreign body
- Temperature > 101°F
- Need for continuous nebulizer treatment, bilevel positive airway pressure, or heliox
- Positive electrocardiographic changes or cardiac biomarkers

Inclusions (appropriate to refer to observation if all criteria are met)
- Shortness of breath
- Mild to moderate use of accessory muscles
- Wheezing
- Fair to good air exchange
- Stable vital signs
- Normal mentation

*Note: These criteria are based on the authors' expert opinion.

www.ketabpezeshki.com 66485457-66963820

include a previous ED visit in the past 10 days, previous intensive care unit admission or intubation, hospitalization during the previous year, three or more ED visits in the past 6 months, use of oral steroids for more than half of the previous year, and peak flow after the third beta-agonist treatment that is less than 32% of predicted.[2]

Therapy in the observation unit is a continuation of ED treatment with hand-held nebulized beta-agonists every 2 to 4 hours and repeated steroids at 6 hours after initial therapy. Patients are managed up to 23 hours but generally are admitted to the hospital if they do not respond within 12 hours. Patients are released from the observation unit when they are no longer in respiratory distress, have minimal residual symptoms, and have a PEFR of 70% or more of predicted or personal best. Before discharge, there should also be patient educational activities and assessment of inhaler techniques. Patients should be initiated into daily diary keeping as well as a log of PEFR before and after treatment. Appropriate follow-up care should also be arranged.

A prospective randomized clinical trial of observation versus traditional hospitalization of ED asthma patients who did not "break" in the first 3 or 4 hours of ED treatment found no difference in relapse rates at 8 weeks, but it found observation unit care to be associated with diminished length of stay (9 hours vs. 59 hours), increased patient satisfaction and quality of life, and cost savings of $1000 per patient.[2,100] Observation unit patients report greater overall satisfaction and fewer problems with their medical care, communication, emotional support, physical comfort, and special needs.[100] Observation has also been shown to have utility in the management of pediatric patients with asthma. Of those who would otherwise require hospitalization, 30 to 70% can be successfully managed as outpatients with the observation unit.[101]

Atrial Fibrillation

Traditional Approach. Atrial fibrillation, a relatively common condition that occurs in 2 or 3% of adults, is the most common sustained cardiac dysrhythmia in patients presenting to the ED.[102,103] The goals in management of acute atrial fibrillation are hemodynamic stabilization, symptom relief, prevention of thromboembolism, resolution of the dysrhythmia, and exclusion of serious pathologic causes of the dysrhythmia. The majority of patients who present to the ED with new-onset atrial fibrillation or acute atrial fibrillation are hospitalized.[80]

Problem with Traditional Approach. Recently, the necessity of admitting the majority of patients with acute atrial fibrillation has been questioned. It is recognized that new-onset atrial fibrillation for most patients is a transient dysrhythmia with no serious precipitants and a benign prognosis. One retrospective analysis of 216 patients admitted for atrial fibrillation found that one third of patients did not actually require admission to the hospital.[104]

Observational Approach. The observational approach to new and acute atrial fibrillation has been validated in a number of clinical trials including a randomized clinical trial.[105,106] The period of observation is usually 8 to 12 hours. During observation, patients are treated to rectify their dysrhythmia and evaluated for serious precipitants of their condition. After observation, 80 to 90% of patients can be discharged home without hospitalization.

For selected patients (Box 195-6), observation extends the ED evaluation of the patient for serious underlying medical conditions that may have precipitated the arrhythmia, such as AMI or hyperthyroidism. AMI is excluded as a precipitant with serial ECGs and cardiac biomarker testing during 6 to 9 hours and an evaluation for unstable angina. The period of observation is also used to detect structural heart disease with the use of echocardiography when it is appropriate. Patients are excluded from observation if they exhibit hemodynamic instability, comorbid conditions, heart failure, chest pain, or evidence of active coronary artery disease.

Observation is also used to extend the treatment period of the patient. The spontaneous conversion rate for patients with acute atrial fibrillation is 50 to 70% within the first 24 hours.[107] Patients who spontaneously convert have a low rate of structural heart disease.[107] Those who do not spontaneously convert in the first 8 hours can be converted chemically or electrically.[108] After cardioversion, the patient needs to be observed. This is especially true for patients converted with the newer class III antidysrhythmic agents (e.g., ibutilide), which have the potential for serious side effects, such as torsades de pointes (5% of patients), sinus bradycardia, and sinus arrest.[108,109] The risk of thromboembolism in patients with atrial fibrillation of less than 48 hours' duration is less than 1%, so patients who convert can be released home without need for anticoagulation.[110]

Box 195-6 Observation Criteria for New-Onset Atrial Fibrillation*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)

- Evidence of new or acute on chronic congestive heart failure
- Past history of structural heart disease
- Abnormal hematocrit level < 30%, elevated B-type natriuretic peptide or pro-B–type natriuretic peptide level, positive cardiac biomarkers, or abnormal electrolyte values
- Evidence of injury or ischemia on electrocardiography or documented or highly suspected unstable dysrhythmia
- Low oxygen saturation or unstable vital signs
- Stool positive for blood
- New focal neurologic findings or persistently altered mental status
- High or moderate probability of serious, dangerous disease or adverse event

Inclusions (appropriate to refer to observation if all criteria are met)

- Low probability of serious, dangerous disease or risk of adverse event
- Stable vital signs
- Normal electrolyte values and blood count
- No positive cardiac biomarkers

*Note: These criteria are based on the authors' expert opinion.

Congestive Heart Failure

Traditional Approach. CHF is highly lethal; 37% of men and 33% of women die within 2 years of diagnosis. The 6-year mortality rate is 82% for men and 67% for women, which corresponds to a death rate fourfold to eightfold higher than that of the general population of the same age.[111] Patients who present to the ED with CHF undergo history taking, physical examination, and investigations including chest radiography. Treatment is begun with oxygenation, diuretics, inotropic agents, and vasodilators as appropriate. Most CHF patients treated in the ED are eventually hospitalized.

Problem with Traditional Approach. CHF is highly prevalent, affecting approximately 1% of people in their 50s and increasing progressively with age to afflict 10% of people in their 80s.[111] More than 2 million Americans have the disease, and 400,000 new cases are diagnosed each year.[111] One third of patients require hospitalization each year, one third are readmitted each year, and one third die within 2 years.[111] The annual cost to the health care system of managing patients with heart failure admitted to the hospital has been estimated at $28 billion.[69] Between 80 and 87% of patients diagnosed with CHF are hospitalized.[112,113]

www.ketabpezeshki.com 66485457-66963820

Box 195-7 Observation Criteria for Heart Failure*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)

Diagnostic electrocardiographic changes or positive cardiac biomarkers
Concomitant acute severe medical condition (e.g., acute renal failure or sepsis)
Moderate or high probability of serious, dangerous disease or risk of adverse event
Unstable vital signs
New-onset heart failure
Severe anemia (hemoglobin < 8 g/dL; hematocrit < 24%)
Anasarca
New arrhythmia

Inclusions (appropriate to refer to observation if all criteria are met)

High likelihood of successful treatment < 24 hours
Symptom of congestive heart failure (e.g., shortness of breath, dyspnea on exertion, paroxysmal nocturnal dyspnea, weakness)
Sign of congestive heart failure (e.g., edema, jugular venous distention, B-type natriuretic peptide > 100 pg/mL, abnormal chest radiograph)
Low probability of serious, dangerous disease or risk of adverse event

*Note: These criteria are based on the authors' expert opinion.

Observational Approach. Observation is a strategy to avoid hospital admission of patients with CHF that results in great cost savings. Selected patients can be safely managed in an observation unit (Box 195-7).[112-114] Such patients include those with a high probability of successful treatment with short-term extension of the ED visit. Patients should also have low severity of illness. They should exhibit hypoxia, pulmonary edema, hypotension, evidence of AMI, hemodynamic instability, or serious comorbid conditions.[112-114] BNP has been used to streamline decision-making. Patients with BNP levels between 100 and 500 pg/mL are suitable candidates for observation unit care because a large proportion of these patients should be able to be discharged home. The test has a negative predictive value of more than 95% and a positive predictive value of 70 to 95%. It correlates with pulmonary capillary wedge pressure, and because its half-life is less than 30 minutes, serial measurements during observation can evaluate the effects of therapeutic interventions.[115,116]

Therapy and evaluation are a continuation of the initial 2- to 4-hour ED visit for up to 23 hours. Continuous electrocardiographic monitoring is performed because up to 30% of CHF patients have dysrhythmias.[117] Inotropic agents can be infused and the patient educated about preventable causes of the exacerbation. Therapy may include continuous infusion of a loop diuretic (0.05-0.1 mg/kg/hr) titrated hourly to a net fluid balance of −1 mL/kg/hr. In most patients with acute exacerbation of chronic CHF, the cause of the exacerbation is preventable, such as failure to take medications or dietary indiscretion. The opportunity to provide patient education, medication review, and consultations with dietary and social services as necessary is fully used because this has been shown to improve compliance with therapy.[118] Patients are discharged home when their symptoms are adequately controlled, all reversible causes of morbidity are treated or stabilized, and adequate outpatient support and follow-up care are arranged. With observation, the focus of ED care can shift from providing only episodic treatment of CHF patients to providing more comprehensive and preventive care.[118] Compared with acute care hospitalization, observation has a much reduced length of stay and significantly lower costs.[118,119]

Box 195-8 Observation Criteria for Dehydration*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)

Severe dehydration
Moderate or high probability of serious, dangerous disease or risk of adverse event
Unstable vital signs
Sodium concentration < 120 mEq or > 155 mEq
Concomitant acute serious medical condition (e.g., acute renal failure, sepsis)

Inclusions (appropriate to refer to observation if all criteria are met)

Inability to correct symptoms in the emergency department
Inability to take fluids orally

*Note: These criteria are based on the authors' expert opinion.

Dehydration

Traditional Approach. Dehydration is often the presenting symptom of an underlying disease state and can affect patients of all ages. Patients are often admitted for intravenous hydration to correct fluid and electrolyte imbalances or for further diagnostic evaluation.

Problem with Traditional Approach. Patients with dehydration are often hospitalized because short ED visits do not allow full correction of fluid and electrolyte disorders or extensive evaluation for underlying causes. A common cause of ED return visits is dehydration due to initially inadequate therapy and evaluation.[120]

Observational Approach. The goals of observation unit therapy are adequate treatment of fluid and electrolyte abnormalities and identification of the underlying cause of symptoms. Appropriate patients for observation include those with acceptable vital signs and mild to moderate dehydration (Box 195-8). They should have self-limited or treatable causes not requiring hospitalization, with mild to moderate electrolyte abnormalities. Most patients with hyperemesis gravidarum can be treated effectively in an observation unit. Patients unsuitable for observation are those with unstable vital signs, cardiovascular compromise, underlying chronic medical illness, severe dehydration or electrolyte abnormalities, or associated conditions not amenable to short-term therapy (e.g., bowel obstruction, diabetic ketoacidosis, and sepsis). Interventions include intravenous rehydration, serial examinations and vital signs, and antiemetics. The patient is released home when there are acceptable vital signs, resolution of symptoms, tolerance to oral fluids, and normal electrolyte values. Patients who do not fulfill the discharge criteria are hospitalized.

Infections

Pneumonia

Traditional Approach. Each year approximately 600,000 patients are hospitalized with pneumonia, at a cost of almost $4 billion.[121] Many of these patients are admitted after initial ED evaluation. Physicians often rely on subjective criteria, such as clinical appearance, in selecting patients for hospital admission.[122]

Problem with Traditional Approach. There is great variation in the admission rates for pneumonia.[123] Emergency physicians tend to overestimate the risk of death in patients with pneumonia, which has resulted in many low-risk patients being hospitalized unnecessarily.[122]

Observational Approach. Observation is appropriate when the physician is concerned that the patient may not do well as an

Box 195-9 Observation Criteria for Pneumonia*

Exclusions (any criterion indicates too high risk for observation; the patient should be admitted)
Moderate or high probability of serious, dangerous disease or risk of adverse event
Unstable vital signs
Risk factors for poor outcome: immunocompromised, neuromuscular disorder, pulmonary tuberculosis, cystic fibrosis
Health care–associated pneumonia or hospital-acquired pneumonia
Concomitant acute serious medical condition (e.g., acute renal failure, sepsis)

Inclusions (appropriate to refer to observation if all criteria are met)
Stable vital signs
Normal mentation
Low risk by clinical judgment or severity index

*Note: These criteria are based on the authors' expert opinion.

outpatient (Box 195-9). This concern can be based on the physician's clinical judgment or a severity of illness index. Fine and associates[122] developed a prediction rule to estimate which pneumonia patients would be at higher risk for mortality. They reviewed medical records of more than 14,000 patients hospitalized with pneumonia and identified 14 key clinical variables (e.g., age, sex, coexisting illness, vital signs, and mental status) and 7 key laboratory variables (e.g., blood urea nitrogen, glucose, hematocrit, arterial oxygen, and pleural effusion on chest radiograph). They then weighed each of these variables into a cumulative point total Pneumonia Severity Index (PSI) and assigned each patient to one of five mortality risk groups ranging from class I, which includes patients with a low risk (30-day mortality risk < 0.5%) who can be treated as outpatients, to class V, which includes patients with a high risk (30-day mortality risk > 30%) who should be treated as inpatients. Patients in class III are at intermediate risk, and traditionally half are admitted and half are treated as outpatients. By use of the PSI to risk stratify patients, physicians can avoid hospitalization of many low-risk patients.[124] Intermediate-risk patients (class III) are good candidates for a period of observation to clarify their need for hospitalization. Irrespective of the patient's risk as judged by PSI, some patients are not appropriate for observation but should be admitted: those with immunocompromise, pulmonary tuberculosis, high suspicion of pulmonary embolism, or hypoxia (Table 195-1).

During observation, patients are treated with antibiotics, oxygen therapy, and pulse oximetry monitoring. Hydration is given either orally or intravenously. After 10 to 12 hours of treatment in the observation unit, the patient is re-evaluated and a decision about disposition is made. Patients who deteriorate during the observation period or have an oxygen saturation of less than 90% on room air after observation should be hospitalized.

Table 195-1 Use of Pneumonia Severity Index (PSI) for Admission Decisions

Step 1: Assess Arterial Oxygenation for All Patients	
Is pulse oximetry < 90% or Po_2 < 60 mm Hg?	
Yes: Inpatient therapy recommended **No:** Go to Step 2	
Step 2: Are Any of the Following Present?	
Patient 51 years of age or older	
Coexisting medical conditions listed in Step 3	
Physical examination findings listed in Step 3	
Yes: Go to Step 3 **No:** Risk Class I, go to Step 4	
Step 3: Compute Risk Score (Sum of Applicable Points)	
Risk Factor	*Points*
Demographic factors	
Age in years (age − 10 for women)	
Nursing home resident	10
Coexisting medical conditions	
Neoplastic disease	30
Liver disease	20
Congestive heart failure	10
Cerebrovascular disease	10
Renal disease	10
Physical examination findings	
Altered mental status	20
Respiratory rate ≥ 30/min	20
Systolic blood pressure < 90 mm Hg	20
Temperature < 35° C or ≥ 40° C	15
Pulse > 125/min	10
Laboratory and radiographic findings	
Arterial pH < 7.35	30
Blood urea nitrogen ≥ 30 mg/dL	20
Sodium < 130 mEq/L	20
Glucose ≥ 250 mg/dL	10
Hematocrit < 30%	10
Po_2 < 60 mm Hg or O_2 sat < 90%	10
Pleural effusion by chest x-ray	10
TOTAL SCORE (sum of all points)	

Step 4: Recommended Initial Site of Treatment

Risk Score	*Risk Class*	*Treatment Site*
Not applicable	I	Outpatient
<71	II	Outpatient
71-91	III	Observation
91-130	IV	Inpatient
>130	V	Inpatient

Pyelonephritis

Traditional Approach. Pyelonephritis is a serious infection that frequently results in hospitalization for intravenous hydration and antibiotic administration.

Problem with Traditional Approach. Many patients who are admitted with pyelonephritis are judged retrospectively not to have had the condition. In addition, many patients with pyelonephritis are at very low risk for development of complications.

Observational Approach. Observation is appropriate for adult, nonpregnant women who appear to have uncomplicated pyelonephritis. Patients receive an initial dose of intravenous antibiotic, intravenous fluids, antiemetic, and antipyretic. Laboratory tests include complete blood cell count, urinalysis, and urine and blood cultures. Patients who are clinically stable and able to tolerate oral fluids are released home after 12 hours of treatment.

Outpatient management of selected patients with pyelonephritis by observation has been shown to be safe and effective. Only 5 to 25% of patients require hospitalization after the period of observation.[125,126] At 3-week follow-up examination, 2 to 6% have complications and require hospitalization.[125,126] With a period of observation and careful follow-up evaluation, selected patients with pyelonephritis can be successfully managed without hospital admission.[126]

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- Hospitalization can be avoided by short-term (<24 hours) treatment of patients in an observation unit for certain medical disorders: abdominal pain, chest pain, DVT, upper gastrointestinal bleeding, syncope, TIA, trauma, asthma, atrial fibrillation, CHF, dehydration, pneumonia, and pyelonephritis.
- Use of observation units results in both cost savings and improved patient satisfaction with care.

Chapter 196

Emergency Ultrasound

Vivek S. Tayal

PERSPECTIVE AND DEFINITIONS

Emergency ultrasound (US) is the simultaneous performance and interpretation of a focused sonographic examination at the bedside of the patient for the diagnosis, resuscitation, monitoring, guidance, and treatment of emergency medical conditions.[1,2]

Emergency US is an emergency clinician–performed study.[1,3] Although the operator is typically an emergency physician, he or she may be an emergency physician assistant, nurse practitioner, or trained emergency nurse or paramedic—all under the supervision of a trained, credentialed emergency physician.[4-6] Emergency physicians who have advanced training in US imaging are also known as emergency sonologists.[6] Emergency US is typically performed in the emergency department (ED) but may also be performed in other areas of the hospital, emergency stand-alone centers, out-of-hospital mobile transport (such as ambulances and helicopters), disaster scenes, military engagements, international rescue work, and remote settings (such as space, sea, or land centers with limited or no medical access).[7-13]

With emergency US, the physician or clinician (1) performs, (2) simultaneously interprets the examination, and (3) integrates the results in the clinical scenario.[1,5] This is unlike other specialties, in which a trained technologist performs the examination and a physician interprets or "reads" the images.[5,14]

Emergency US examinations are focused examinations of an area of the body, organ system, or physiologic pattern or goal-directed investigations of an emergency symptom or sign. Not all pathologic processes will be detected by such examinations, usually because of the interference of acoustic entities that reduce transmission and reflection of sound and the lack of an appropriate window to the tissue of choice. Other limitations include experience, skill, and confidence of the performing physician.[15] The main risk management issue associated with emergency US is not using the modality when it is available and appropriate.[16]

HISTORY

A half-century of scientific work in many countries produced the initial medical uses of US in the 1950s by physicians interested in its advantages over traditional imaging, including noninvasiveness, lack of ionizing radiation, and superior resolution.[14] In the 1980s emergency physicians started to use US as a way of ruling out emergent "silent" diagnoses, such as ectopic pregnancy, intraperitoneal hemorrhage, hemopericardium, cholelithiasis, renal colic, and aortic aneurysm. A model curriculum was created by the Society for Academic Emergency Medicine (SAEM) that initiated formal guidance for emergency US programs.[17,18] Because of resistance from traditional imaging specialties, such as radiology and cardiology, the American Medical Association House of Delegates, led by the American College of Emergency Physicians (ACEP), passed a resolution that hospital credentialing committees follow specialty-specific guidelines for US-based credentialing.[19]

Specialty-specific guidelines, created in 2001 and updated in 2008 by the ACEP and endorsed by the SAEM in 2010, specify emergency US scope of practice, primary applications, training pathways, number of procedures required for training before credentialing, quality assurance and documentation guidance, and training course outlines.[1] Today, more than 95% of emergency medicine residencies teach US, and approximately 30 to 60% of community hospitals have instituted bedside US performed by emergency physicians.[20,21]

Since 2008, emergency US has been recognized by outside organizations, including the American Institute of Ultrasound in Medicine, with implementation of the focused assessment with sonography for trauma (FAST) examination, and the American Society of Echocardiography, with application of focused cardiac US (FOCUS) for shock, effusion, chest pain, and cardiac arrest.[22,23] Several other organizations have recognized emergency or point-of-care US, including the World Interactive Network Focused on Critical Ultrasound internationally and the Society of Medical Ultrasound in Medical Education for medical education.

US programs typically require some investment in education and hardware, but reimbursement for both professional and hospital fees is adequate to meet return on investment within years, depending on number and types of US, payer mix, and documentation.[24] More EDs have recently invested in digital-based archiving and storage systems. The more traditional solution is the picture archiving and communication system. A new, more comprehensive solution seems to be the web-based US management systems, which provide archiving, documentation, quality assurance, and credential solutions to the emergency medicine and point-of-care market.

TRAINING, CREDENTIALING, AND ACCREDITATION

Emergency US is one of the competency assessments required of emergency medicine residents by the Residency Review Committee for Emergency Medicine, with defined requirements as set by national organizations.[25-27] For emergency physicians in practice, initial training often takes place through nationally defined hands-on continuing medical education courses followed by a period of proctoring or supervision.[1,28] Credentialing at the hospital level is based on specialty-specific national guidelines. Recent educational advances, such as simulation, task trainers, and web-based training, enhance US training.[29-32] US is not defined as advanced imaging by the Centers for Medicare and Medicaid

www.ketabpezeshki.com 66485457-66963820

Services or the 2008 Medicare Improvements for Patients and Providers Act.[33]

Medical student emergency US education has also been defined by national organizations and may be incorporated in more extensive undergraduate US programs.[1] US fellowships have become the most prevalent postgraduate emergency medicine fellowship.[34] See the website of the American College of Emergency Physicians (http://www.acep.org/Clinical–Practice-Management/Ultrasound/; accessed April 12, 2013) for helpful references for program development and education.

APPLIED ULTRASOUND PHYSICS AND INSTRUMENTATION

By definition, US is sound with frequencies higher than 20,000 Hz. US is kinetic energy, a longitudinal, mechanical, and directional wave, so all users of this technology should observe the ALARA (as low as reasonably achievable) principle by performing procedures only when they are needed and limiting the time of sonographic investigation.[35]

US waves are characterized by their amplitude (deflection from a baseline), wavelength (the wave cycle distance, usually measured in microns), and frequency (the number of cycles per second). Modern diagnostic US transducers emit at millions of cycles per second or megahertz. Lower frequencies penetrate deeper tissue at the expense of resolution, whereas higher frequencies improve resolution but cannot penetrate deeper structures.

M-mode or motion mode displays received waves over both time and distance and is used to calculate rates, speeds, and distances by sending a steered one-dimensional line across tissue. The most familiar display is *B-mode* or brightness mode, which graphs the amplitude of reflected US waves as shades of gray from black to white on a monitor screen. As sound hits reflective interfaces, it returns to the transducer at higher amplitudes than waves that continue through tissue. In addition, sound can be attenuated, refracted, and reverberated away from the transducer. These reflections or lack thereof create a brightness graph that is depicted in two planes, creating the two-dimensional image. One can adjust the brightness of the image by changing the overall gain or by changing the amount of gain at certain depths, which is called *time-gain compensation* (TGC). This allows a more discrete amplification of sound at different levels. By increasing overall gain or amplification and TGC at different levels, one can adjust for the loss of returning information.

US resolution can be described as axial, in the long axis of the transducer, or lateral, perpendicular to the long axis of the transducer. Typically, higher probe frequencies produce higher axial resolution. The focus of the transducer is the image area where the US beam produces the best lateral resolution. The area from the probe to the focus is called the near field, and that from the focus to the end of the image is called the far field. The best imaging with maximum reduction in artifacts occurs at the focus.

Focal zones can be increased for more resolution, but frame rate (the speed at which the screen updates the image) will decrease, causing a slow-motion image that is poor for imaging of moving tissues. One can also change from a sector transducer (a curved abdominal or phased array transducer) to a linear transducer for better lateral resolution on the edges of the transducer.

Some machines allow the adjustment of *dynamic range,* which is the ratio of initial intensity and final intensity of returning echoes. Adjustment of dynamic range allows more contrast (e.g., echocardiography) or more gray scale (e.g., soft tissue). Harmonics is another technology that listens for multiples of the frequency sent out and often cleans up images near the screen, such as in the gallbladder, apex of the heart, or soft tissue of skin.

Doppler US shows the velocity of moving structures, typically red blood cells, thus representing flow. *Color flow Doppler* shows direction (by red or blue colors representing flow in opposite directions) and velocity of flow (by degrees of brightness of the color, where lighter is higher velocity). Power Doppler or power angiography is also a representation of velocity of flow, but it describes only the presence of flow and not direction.

Box 196-1 Common Definitions

Window: soft tissue where transducer is placed to interrogate tissue in the body
Anechoic: without sounds (black)
Echogenic: with sounds (white)
Hyperechoic: with more reflected sounds than adjacent tissue (more echogenic)
Hypoechoic: with less sound than adjacent tissue (less echogenic)
Shadowing: sound blocked by a reflective barrier
Enhancement: more echogenicity due to increased velocity of sound, typically behind a fluid-filled structure, such as the bladder or gallbladder
Reverberation: an artifact that results from multiple reflections at a given interface, often in parallel
Mirror image: a propagation speed artifact that repeats images that are beyond a strong reflector (e.g., diaphragm), creating a mirror image
Lateral cystic shadowing: a refraction artifact seen on the edge of cystic structures, causing an artificial shadow
Beam width artifact: a volume-averaging artifact causing artifactual echoes in the inferior aspect of anechoic structures or spaces

Gray scale US has the best resolution when the direction of the probe and the sound waves are perpendicular to the object because the sound is reflected up to the transducer. Doppler US has the best resolution with the probe parallel to or less than 60 degrees from the direction of blood flow. This often means realignment by tilting of the probe to create better imaging based on the mode of US.

Other US terms and artifacts commonly used are listed in Box 196-1.

EQUIPMENT AND SAFETY

A variety of US machines are available, including palm size, laptop, cart based, and combination devices. US machines have controls for gain, depth, and freeze and have print or acquire image controls. Additional controls include TGC, frame rate, measurement, dynamic range, M-mode, power Doppler, color directional Doppler, spectral Doppler, patient identification, transducer selection, and image review. Images are produced in digital stills, digital video clips, thermal paper stills, or DVD or video recordings.

Modern multifrequency probes can select among several US frequencies to maximize either tissue penetration or image quality, depending on the application. Probe design and footprints (the actual transducer surface area touching the patient) can be divided into three categories: flat linear array probes, curved linear array probes, and phased array probes. *Flat linear probes* give a square or rectangular picture with excellent lateral resolution at the expense of width of field. *Curved linear array probes,* which give a wider field of view at the expense of lateral resolution, are usually used for deep tissue penetration applications, such as evaluation for pregnancy or abdominal aortic aneurysm. The *endocavitary probe* is a highly curved linear array probe that is most commonly used for endovaginal evaluation. *Phased array probes* offer a smaller footprint than curved linear array probes and were originally developed for cardiac evaluations, but they can also be used for abdominal studies. They offer excellent image quality for the evaluation of moving structures but with worse resolution of

www.ketabpezeshki.com 66485457-66963820

static structures. Transesophageal echocardiographic, three-dimensional, and biplanar probes are recently being used in emergency US, creating new imaging venues.

US biosafety, including use of the ALARA principle, appropriate Doppler technology, and appropriate microbiologic disinfection of the probe, has been reinforced by recent articles.[36] The ALARA principle suggests that the least amount of energy be used to produce satisfactory imaging. Doppler modes should be minimized over sensitive tissue, including early gestation, germinal tissue, and mucosal or neural tissue. The sonographer should be familiar with the thermal index (TI), which should be kept below 2.0, and the mechanical index (MI), which should be kept below 1.9. Surface probes should be cleaned at the bedside with mechanical removal of the gels and debris and then disinfected with an appropriate spray or wipe. Endocavitary probes will need more prolonged and substantial cleaning. Safety also includes the use of appropriate barriers over transducers, including condoms, gloves, or commercial barriers over endocavitary probes and sterile transducer covers for sterile procedures.[37] For nonsterile procedures, barriers can include translucent sterile transdermal barriers.

APPLICATIONS AND CATEGORIZATION

In 1994 the SAEM categorized US applications broadly into abdominal, cardiac, obstetric-gynecologic, and special applications.[17] In 2001 the ACEP developed guidelines that categorized applications more specifically to include trauma, pregnancy, abdominal aortic aneurysm, cardiac (for pericardial effusion and cardiac activity), biliary, renal, and procedural guidance.[38] In 2008 the ACEP added deep venous thrombosis (DVT), thoracic studies for pneumothorax and pleural effusion, soft tissue and musculoskeletal studies, and ocular examination as core appplications.[1] Advanced applications at that time included testicular, adnexal, bowel, advanced echocardiography, transesophageal echocardiography, transcranial Doppler, and contrast studies. Therapeutic applications of transcranial Doppler are being studied by emergency physicians.[39] Grouping of these US applications into categories of resuscitative, diagnostic, symptom or sign based, procedural guidance, and monitoring and therapeutic helps describe the relationship between the uses of US in emergency medicine (Table 196-1).

The most common uses of emergency US in decreasing order are trauma, cardiac (cardiac arrest and pericardial effusion), abdominal aortic aneurysm, pelvic, biliary, procedural, renal, and DVT.[21] Among recent emergency medicine residency graduates, US use was high (98%), with those in academic centers reporting highest use.

US guidance can assist many percutaneous procedures, such as vascular access, torso cavities evacuation (e.g., thoracentesis, paracentesis, and pericardiocentesis), arthrocentesis, lumbar puncture, abscess drainage, nerve blocks, and others.[3] Emergency US is used in clinical pathways or algorithms to identify or to exclude emergency medical conditions rapidly.[40,41]

Trauma Ultrasound

The trauma US examination is also called the focused assessment with sonography for trauma (FAST) examination.[1,22,42] The trauma examination originally focused on the peritoneal space, as an evaluation for hemoperitoneum, with use of the right flank, left flank, and pelvic windows for detection of dependent peritoneal fluid and pleural effusion.[43] Newer versions include the EFAST (extended FAST) for the evaluation of potential pneumothorax and FASTER for evaluation of the extremities.[40,44-46]

The FAST examination is based on the premise that a treating physician can sample known sonographic windows within minutes to evaluate the peritoneal, pericardial, and pleural spaces for fluid and abnormal fluid and air. Within the peritoneum, fluid circulates throughout the abdomen and pelvis and settles in dependent spaces.[47,48] The volume of fluid required for a positive US study depends on the site of injury and site of sonographic detection, but 250 mL or more is generally visible, and nearly 600 mL of fluid is necessary to cause a positive flank stripe when fluid is infused from the pelvis.[49]

Pericardial fluid is contained within the parietal and visceral pericardium. Once a certain volume is reached, the pressure in the pericardial space increases exponentially, causing pericardial tamponade.[50] In general, 50 mL is required to cause hemodynamic compromise in a patient without prior pericardial inflammation. However, tears in the pericardium that communicate with the pleural space or even the peritoneum can cause false-negative examination findings.

Pleural fluid can be detected by US, but this depends on the position of the body.[51] Pneumothorax detection is based on the absence of the normal sonographic sliding of the visceral and parietal pleurae, although there are other signs (see thoracic section).

The torso trauma US examination (often called the EFAST) can detect pathologic free intraperitoneal fluid (typically hemoperitoneum, uroperitoneum, bile, or ascites), hemopericardium, hemothorax, or pneumothorax.[45,46] Typically, fluid in the peritoneum, pericardium, and pleural cavity is anechoic, but it can have echogenicity with clotting, depending on the age of the clot or bowel contents. Compared with other fluid-filled structures in the abdomen and pelvis, peritoneal free fluid generally has sharp edges and an irregular shape, whereas most visceral or vascular structures have intrinsically smooth oval contours and less abrupt edge detail.

The FAST technique uses a low- to middle-frequency probe (2-5 MHz) to evaluate dependent peritoneal spaces, pleural spaces,

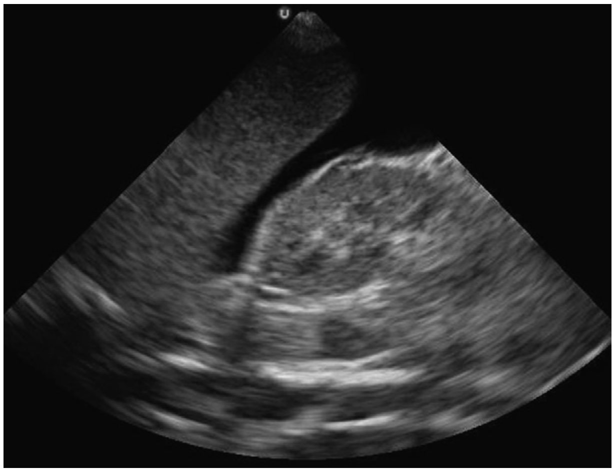

Figure 196-1. Free fluid in the peritoneum in Morison's pouch seen from right flank.

and the pericardium. Within the peritoneum, dependent spaces include the following, grouped by tissue window: the right flank, which evaluates the hepatorenal space (also called Morison's pouch; Fig. 196-1), the right subphrenic space, and the right costophrenic angle; the left flank, which evaluates the perisplenic space between the diaphragm and spleen, the splenorenal space, the perirenal space, and the left subphrenic space; and the suprapubic view, which is performed by placement of the transducer superior to the pubic bone with a full bladder to visualize the pouch of Douglas in women and the retrovesical space in men. Extra views include the paracolic gutters inferior from the flank views and medial from the iliac spine to visualize free fluid surrounding the bowel.[52]

The typical cardiac views include the transverse subcostal images, which visualize the four cardiac chambers and pericardial space, and the sagittal subcostal view to assess the pericardial space and the collapsibility and diameter of the inferior vena cava (IVC), indicating right-sided heart pressures. A good alternative in patients with long chest walls or obesity is the parasternal view, which assesses the anterior and posterior pericardial spaces.

For pleural fluid, the superiorly angled flank views allow visualization of the costophrenic angles. The evaluation for pneumothorax uses either a low-frequency probe at a shallow depth or, more typically, a high-frequency probe for better resolution, placed at the anterior chest in the second intercostal space for anterior pneumothorax and at the axilla for large pneumothoraces and pleural effusion. Diaphragm injuries have been described with dislocation of typical organ patterns.[53]

The sensitivity of the FAST examination ranges from 60 to 99%, and its specificity ranges from 80 to 99%.[54-57] The large range of sensitivity is related to the comparative "gold standard" used for each study, with clinical endpoints suggesting higher accuracy. The FAST does not capture every peritoneal injury, although the need for intervention in undetected injuries has not been studied.[58] Randomized, controlled trials show lower morbidity, time to operating room, and charges for patients with US use during resuscitation, and a positive US study increases the odds ratio for laparotomy.[59,60]

Patients with traumatic pericardial effusions are taken to the operating room sooner and have lower mortality rates with US.[44] However, the mediastinal injuries more common in blunt trauma have not been assessed without transesophageal echocardiography.[50,61] US can diagnose pneumothorax with excellent sensitivity and specificity compared with plain chest radiography

Figure 196-2. Intrauterine pregnancy with fetus on endovaginal scanning.

and variable accuracy compared with computed tomography scanning.[62,63]

There are certain populations of patients in whom FAST evaluation has limited benefit. With penetrating chest injuries, the FAST examination seems to be efficacious for both pericardial and nearby peritoneal injuries; but in patients with purely anterior penetrating trauma to the abdomen, the sensitivity of trauma US is poor because bowel injuries can occur without significant hemoperitoneum.[58,59,64-66]

The accuracy of the FAST examination may be lower in children than in adults, and many pediatric injuries can be observed or treated nonoperatively with angiography.[67] In obstetric patients, the few observational studies that have been performed have shown reasonable sensitivity and specificity, although abruption and fetal viability may necessitate an earlier operative course.[68]

With pelvic fractures, the sensitivity ranges from 20 to 80%.[69-72] More important, the detection of free fluid in an unstable patient with a pelvic fracture may be due to uroperitoneum from bladder injury rather than hemoperitoneum from vascular injury, clouding the decision for laparotomy versus pelvic embolization.[64] In addition, retroperitoneal injuries to the genitourinary tract are not assessed with four-quadrant FAST examination.

Pelvic Ultrasound

Pelvic US by emergency physicians was initiated to address one of the epidemics of the modern era—ectopic pregnancy.[73-77] Typically, pelvic US is used to confirm intrauterine pregnancy, which indirectly excludes ectopic pregnancy in most patients.[78,79] A recent meta-analysis revealed a pooled sensitivity of 99.3% to rule out ectopic pregnancy when an intrauterine pregnancy was detected. Another use during pregnancy is the detection of fetal viability, incomplete abortion, ectopic pregnancy, and molar pregnancy. Pelvic US is used in nonpregnancy states to detect tubo-ovarian abscesses, masses, and hemoperitoneum in the hemodynamically unstable patient.[80]

Indications for sonographic evaluation of the first-trimester pregnant patient include symptoms or signs that suggest an ectopic pregnancy, molar pregnancy, or fetal demise and dating of the pregnancy. Intrauterine pregnancy is confirmed with a gestational sac with a yolk sac or fetal pole within the fundus of the uterus (Fig. 196-2).[78] An embryonic or fetal demise has US findings of a fetal pole measuring more than 5 mm without fetal heart rate or a gestational sac of more than 20 mm in diameter without a fetal pole. A molar pregnancy appears as an echogenic, cystic uterus with disorganized echoes and is associated with high β-human chorionic gonadotropin concentrations without the sonographic finding of intrauterine pregnancy. Findings of an ectopic

www.ketabpezeshki.com 66485457-66963820

pregnancy include a chorionic ring or gestational sac with evidence of a yolk sac or fetal pole outside the uterus or in an abnormal location in the uterus, such as the cornu or cervix.[73] Excluding the groups of intrauterine pregnancy, embryonic demise, molar pregnancy, and ectopic pregnancy, there is a class called indeterminate, which may account for 20% of pregnant patients presenting to the ED in the first and early second trimesters. Heterotopic pregnancies can occur at a rate of 1/5000 and be detected by the same techniques and definitions.[81]

Pelvic US is performed by transabdominal or endovaginal techniques. The transabdominal technique uses a low-frequency transabdominal transducer placed over the lower abdomen suprapubically. Ideally, the patient has a full bladder, which provides a sonographic window, but this may not be necessary if the uterus is large or the patient is thin. Advantages of the transabdominal technique include wider field of view, detection of large pelvic masses, and greater depth of field. In the endovaginal technique, the transducer is placed in the vagina, optimally with an empty bladder to visualize the same structures. Endovaginal transducers are high frequency, providing excellent axial resolution but poor penetration of distant structures. Early intrauterine yolk sacs and fetal poles within gestational sacs may be detected more clearly, and ectopic pregnancies can be identified with more accuracy. Endovaginal US can detect small (7 mL) amounts of peritoneal fluid. Endovaginal US in the hemodynamically compromised patient has replaced culdocentesis for detection of ruptured ectopic pregnancy.

Emergency physician–performed pelvic US has reduced the morbidity of ectopic pregnancy by shortening the time to diagnosis and operating room treatment and has resulted in greater initial detection of abnormal pregnancy, reduced ED patient throughput times, and increased patient satisfaction with care.[74,76,82-85] The detection of live intrauterine pregnancy predicts a rate of 91% continuation past 20 weeks, except for those with vaginal bleeding, who drop to a rate of 86%.[86] Further continuation of the pregnancy to term occurs in 77% of patients.[87] Emergency physicians can date pregnancies accurately by pelvic US with typical fetal biometry.[88]

Emergency physicians are adept at identification of ectopic pregnancies by both transabdominal and endovaginal techniques.[85,89-93] In addition, molar pregnancies and some malformation, such as conjoint twins, have been described.[94,95] The gynecologic differential diagnosis of significant free fluid in a pregnant woman, in addition to ectopic pregnancy, should include uterine rupture and ruptured corpus luteum pregnancy.[96] Pelvic US in nonpregnancy states has shown good accuracy for tubo-ovarian abscess and improved decision-making for female patients with right lower abdominal pain.[97,98]

Cardiac Ultrasound

The use of cardiac US by emergency physicians is presentation and symptom specific and focused in nature. Indications include cardiac arrest, possible pericardial effusion, trauma, chest pain, hypotension, and procedural guidance.[1,3,23,99] Cardiac US is often included in algorithms and protocols for certain symptoms or signs, such as dyspnea or hypotension.

Cardiac US is performed through the transthoracic and transabdominal windows with use of small curvilinear or phased array transducers. Typical views include the subcostal four-chamber and long-axis views, parasternal long-axis view, parasternal short-axis view, and apical four-chamber view. Although most emergency physicians are comfortable with the subcostal view from the FAST examination, the parasternal long-axis view is a good alternative and good window for left ventricular assessment.[100,101] In addition, the apical four-chamber view provides excellent comparison of the right and left ventricles in terms of size and function. The long-axis subcostal view shows some of the right side of the heart but highlights the IVC, including size and respiratory variation.

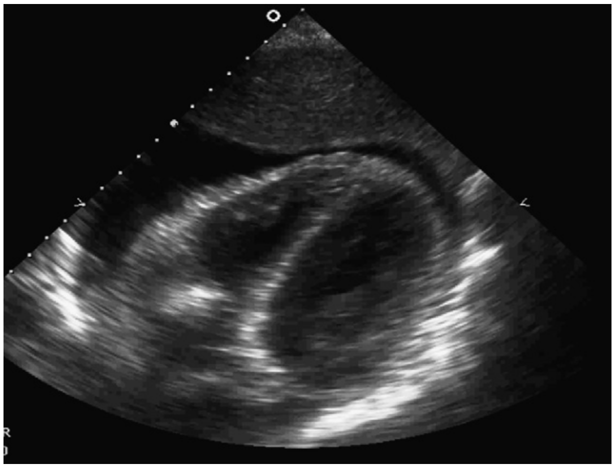

Figure 196-3. Pericardial effusion in subcostal view.

Cardiac US performed by emergency physicians shows good accuracy in detection of pericardial effusion (Fig. 196-3), assessment of left ventricular function, and evaluation of patients with undifferentiated shock. In addition, aspects of cardiac US are being used for the assessment of intravascular volume status and cardiac output and in the evaluation of dyspnea.

In cardiac arrest, US can detect ventricular motion in both asystole and pulseless electrical activity (PEA).[102,103] In asystole, two studies have shown poor prognosis in the absence of sonographic ventricular activity.[84] Cardiac US can detect pseudoasystole by revealing ventricular fibrillation or coordinated cardiac contractions without a palpable pulse.[85,104] Use of cardiac US in PEA and near-PEA states can be diagnostic for pericardial effusion.[82] Cardiac US can detect ventricular capture when the patient is paced, transcutaneously or by a transvenous pacer. US can also identify pneumothorax, another treatable cause of cardiac arrest.[103] Cardiac US is feasible during pulse checks and prehospital life support, as advanced cardiac life support guidelines suggest minimizing non–cardiopulmonary resuscitation intervals.[105-108]

Emergency cardiac US is diagnostic for both medical and traumatic pericardial effusions.[109,110] In patients with dyspnea, pericardial effusion is detected with excellent accuracy.[111] In trauma, use of cardiac US reduces time to operative intervention and reduces mortality in patients with penetrating cardiac injury.[50] Detection of effusions in blunt trauma has also been described. Patients with cardiac US performed by emergency physicians for pericardial effusion have significantly reduced hospital length of stay and charges.[112]

Cardiac US is used for detection of pericardial effusions, chamber enlargement, and global activity in chest pain syndromes.[113] In chest pain, US has been studied for the evaluation of pericardial tamponade, pulmonary embolus, cardiogenic shock, aortic dissection, pneumothorax, and bony chest wall fracture.[114-116]

US protocols have been developed to evaluate undifferentiated hypotension.[41,117-119] Cardiac US windows with the addition of abdominal views can assess for effusion, global ventricular activity, ventricular chamber size, IVC size and respiratory change, peritoneal fluid, and abdominal aortic aneurysm to narrow the differential diagnosis. Sepsis is the most common diagnosis for patients with hyperdynamic ventricular activity.[120]

Central pressures can be estimated by examination of the IVC size and collapsibility.[121,122] Studies show that this technique has good accuracy in assessment of blood loss, hypovolemia, and congestive heart failure.[123,124] Correlation studies have shown

www.ketabpezeshki.com 66485457-66963820

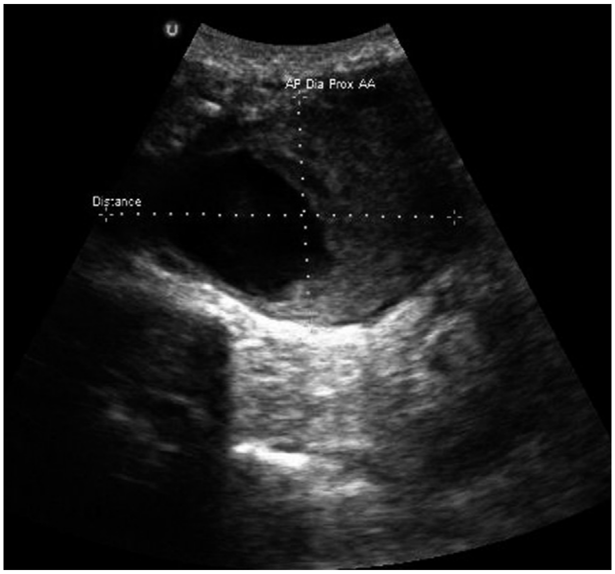

Figure 196-4. Large abdominal aortic aneurysm with echogenic intraluminal clot.

moderate agreement between central venous pressure and IVC measurements, with actual cardiac qualitative assessment as good as or better than the IVC measurements.[125-129] The internal jugular vein measurement may correlate with central venous pressure,[130] and esophageal Doppler examination may also correlate with hemodynamic measurements.[131]

Cardiac US is also a procedural guide for placement of transvenous pacer wires and for pericardiocentesis. Transvenous pacer wires are often placed through central veins, and it can be difficult to place them into the right ventricular apex. US facilitates placement by imaging of the wires in real time as they pass through the tricuspid valve and approach the apex of the right ventricle. US can also document ventricular capture. The probe is placed in the subxiphoid space for both applications.

Abdominal Vascular Ultrasound

Emergency physicians use abdominal US to detect abdominal aortic aneurysm, another silent disease in patients with flank, abdominal, or back pain, and to evaluate unexplained hypotension in the older patient.[132,133] The use of US to detect aortic dissection and occlusion is described as well.[134-136]

The technique involves imaging of the aorta from the subxiphoid space to the umbilicus to evaluate for dilation above a diameter of 3 cm (Fig. 196-4). For the detection of infrarenal aneurysms, the technique should visualize the aorta from the diaphragm to the aortic bifurcation. Fusiform aneurysms are more common, but detection of saccular aneurysms requires both the transverse and longitudinal planes.[137] If an aneurysm is found, a peritoneal view of Morison's pouch is performed to detect intraperitoneal fluid. Proximal iliac arteries may be followed if it is technically feasible or time allows.

Emergency physician use of US for abdominal aortic aneurysm detection has shown good accuracy compared with other imaging modalities and laparotomy.[133,138-140] It also has management implications in older patients with lower back pain, in whom the elimination of the presence of abdominal aortic aneurysm can lead to other management decisions. Screening for abdominal aortic aneurysm in the ED with US has been shown to be effective.[141,142]

Endovascular repair versus the more traditional open repair has become more popular.[143,144] The detection of leaks (often called endoleaks) from the stent would require Doppler imaging and may require further imaging with computed tomography or magnetic resonance imaging.[144]

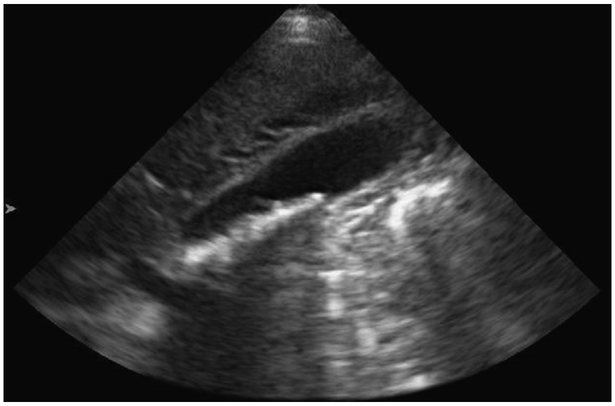

Figure 196-5. Echogenic layering gallstones seen in gallbladder with posterior shadowing.

Aortic dissection may be detected by a combination of abdominal and cardiac scanning.[136] A linear echogenic flap, anywhere across the lumen of the aorta, is suggestive of dissection, sometimes with the detection of different flows on either side of the flap by color Doppler scanning. The cardiac US examination can show unexplained pericardial effusion; a dilated aortic root; aortic insufficiency; and a linear echogenic flap seen in the ascending aorta, aortic arch (through a suprasternal notch), or descending aorta.

Aortic occlusion is another condition that may be detected by US.[145] Echogenic thrombus may fill the aorta and disrupt perfusion below the diaphragm with resulting pain, pallor, numbness, and reduction or absence of distal pulses. Clear identification of the borders and lack of Doppler flow in the abdominal aorta are characteristic of the syndrome.

Biliary Ultrasound

Biliary US to detect gallstones and associated cholecystitis was one of the early applications of US in emergency medicine.[146-148] The sonographic technique involves a modified biplanar approach to the right upper quadrant. A complete evaluation includes visualization of the common bile duct. The diagnosis of cholelithiasis is made after identification of echogenic foci within the gallbladder lumen with shadowing (Fig. 196-5). Other image patterns include stones that will not shadow, sludge, and the wall echo sign of a gallbladder full of gallstones. Signs of cholecystitis include a dilated gallbladder, increased gallbladder wall thickness, sonographic Murphy's sign, and pericholecystic fluid. A nonmobile stone in the gallbladder neck is highly suggestive of eventual cholecystitis.[149] A common bile duct larger than 6 mm in people younger than 60 years and smaller than 10 mm in elders may indicate choledocholithiasis. Biliary US is fast and accurate, with a sensitivity of 87 to 94% and a specificity of 82 to 96% in detection of gallstones, comparable to radiology ultrasonography.[150-153] Biliary US has replaced nuclear medicine testing.[148,154]

Urinary Tract Ultrasound

Renal or urinary tract US can detect hydronephrosis or urinary retention. The lack of ionizing radiation and the rapidity of renal US make it an attractive option for the investigation of unexplained flank, back, or groin pain or abdominal mass.

Renal US includes biplanar views of the kidneys with emphasis on dilation of the calyceal system and pelvis of the respective

www.ketabpezeshki.com 66485457-66963820

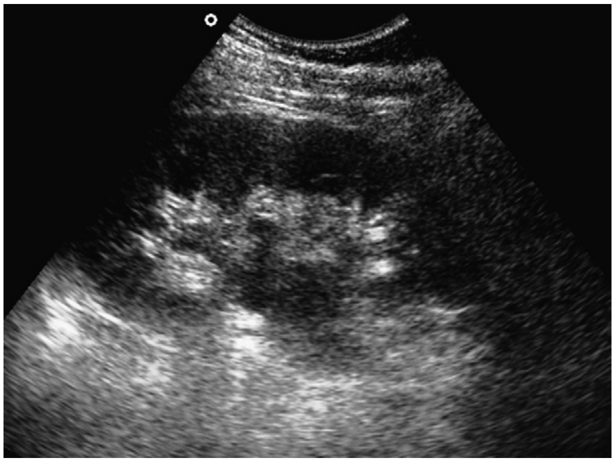

Figure 196-6. Hydronephrosis in renal pelvis and calyces.

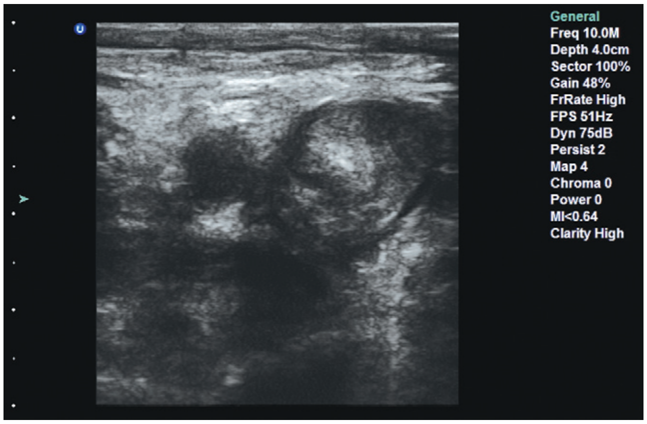

Figure 196-7. Deep venous thrombosis with layering clot in popliteal vein seen on compression ultrasound examination.

kidney (Fig. 196-6). In addition, visualization of the bladder can diagnose secondary hydronephrosis from an obstructed bladder stone and may demonstrate nonobstructive bladder jets through the use of Doppler US. The windows for the two kidneys are similar to those of the trauma flank series, with the exception that the patient may be rolled on the opposite side so that the transducer may be placed more posteriorly on the back if necessary. The bladder view is performed suprapubically, and calculations of volume may be made with on-machine calculators or by formulas.

Renal US has a sensitivity of 83% and a specificity of 92% in detection of hydronephrosis (see Fig. 196-6).[155,156] Genitourinary tract obstruction protocols have great sensitivity in elimination of renal obstruction from a differential diagnosis.[157] Bladder US is useful for detection of a full bladder and the presence of a Foley catheter and for guidance during suprapubic aspiration or Foley placement.[119-124,158-160]

Deep Venous Thrombosis Ultrasound

The swollen extremity often requires sonographic imaging to assess for DVT. Emergency physicians commonly use compression US to rule out DVT.[125-128,161-165] The two-level compression technique involves visualization of the compressibility of the common femoral and popliteal veins. The three-level technique adds the junction of the superficial femoral and deep femoral veins (Fig. 196-7). Use of upper extremity veins is less common because Doppler US is needed for the subclavian vein, which is not compressible under the clavicle.[166]

The accuracy of this technique ranges from 70 to 99%, depending on operator experience.[164,167-169] Hospital charges and time in the ED are reduced for patients who have bedside venous US performed to rule out DVT.[170-172]

Bernardi also investigated a whole-leg strategy versus a 2-point strategy in combination with a D-dimer test, which required 1-week follow-up with an abnormal level.[173] Both strategies were equivalent in detection of symptomatic DVT at 3-month follow-up. Depending on the skill of the sonographer, patient characteristics, and availability of follow-up, ED US may guide lower extremity DVT institutional protocols.

Thoracic and Tracheal Ultrasound

Thoracic applications include the detection of pleural effusion, pneumothorax, pneumonia, and interstitial edema.[174,175] The technique of thoracic US uses a low-frequency probe to survey for pleural effusions and a high-frequency probe to detect pleural

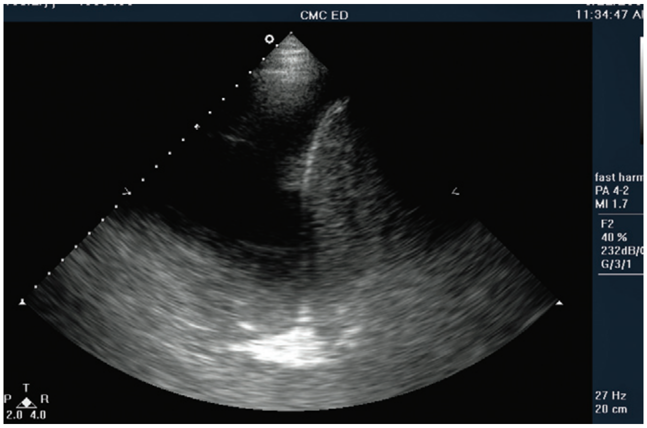

Figure 196-8. Large pleural effusion.

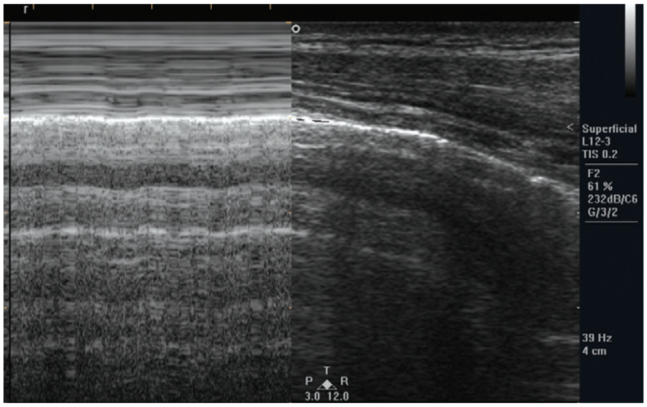

Figure 196-9. M-mode image of normal lung sliding.

lines and related artifacts. Pleural fluid appears as an anechoic collection above the diaphragm (Fig. 196-8). In addition, a collapsed lung may be visualized as an echogenic floating structure. Normally, the parietal and visceral pleural lines slide against each other, and lack of sliding is the finding most consistent with pneumothorax (on M-mode, called the seashore sign). Additional findings of pneumothorax include the presence of horizontal artifacts called A-lines (on M-mode, called the stratosphere sign) and the absence of B-lines (vertical white lines from reverberation of air with fluid) at the parietal-visceral pleural line (Fig. 196-9).[176-179]

www.ketabpezeshki.com 66485457-66963820

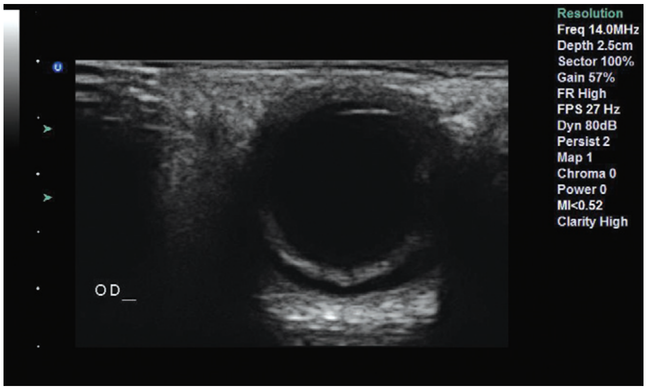

Figure 196-10. Retinal detachment.

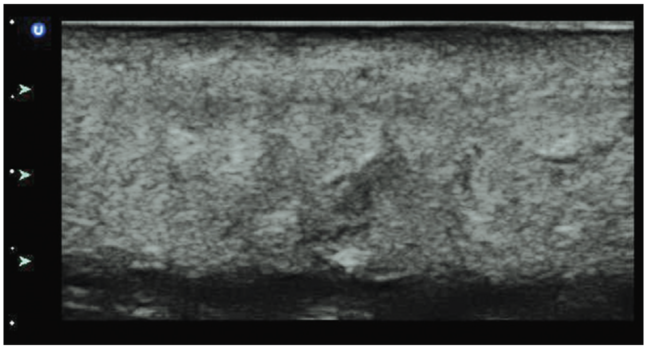

Figure 196-11. Sonographic cellulitis with echogenic subcutaneous tissue.

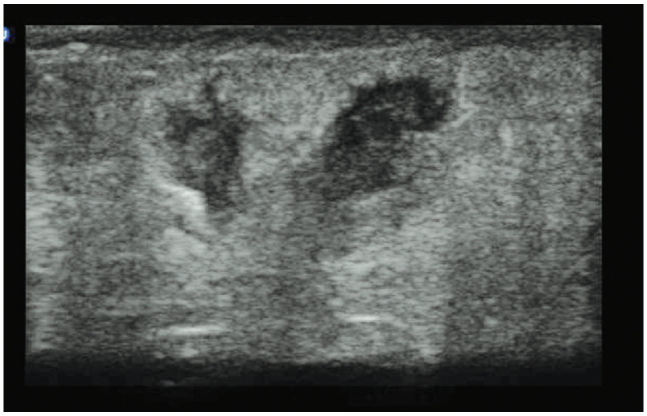

Figure 196-12. Sonographic subcutaneous abscess.

Confounding factors include adhesions of the pleura, chronic obstructive pulmonary disease, prior pneumothorax, and mainstem bronchus intubation. A lung point sign is the edge of the pneumothorax where the lung is still adherent to the parietal pleura, and part of the image shows no sliding until the lung moves into the interspace with respirations.[177] The accuracy of US for detection of pneumothorax (sensitivity 100%, specificity 98%) is better than that of plain chest radiography in the acute setting, but there may be reduced accuracy after 24 hours.[180]

Severe pneumonia is visualized as echogenic "liver-like" echogenicity as the lung accumulates fluid with consolidation.[181] Peripneumonic collections are common and may indicate inflammation. The dynamic air bronchogram, hyperechoic areas within bronchi that move with respiration, usually within "heparinized" lung, has been described as another sign of alveolar consolidation.[182]

Pulmonary edema is indicated by the presence of comet tails (B-lines), which are reverberation artifacts that reflect from the parietal pleural interface into the lung. Normally found in dependent areas of the lung, the widespread distribution of these artifacts in an apical lung may indicate increased lung congestion.[183-185]

Dynamic tracheal US for the confirmation of endotracheal intubation has relatively good sensitivity and specificity.[186-188] The dynamic movement of the endotracheal tube creates a flutter through the recognized shadow of the airway, but static US seems to lack accuracy.[189,190] This technique may have a role in patients in cardiac arrest or with equivocal end-tidal carbon dioxide levels, and confirmation is significantly faster than with chest radiography in children.[190]

Ocular Ultrasound

The eye is an excellent acoustic window, and short-duration gray scale US over a closed eyelid can visualize both the anterior and the posterior chamber well.[191,192] The globe, pupillary size, and extraocular movements can be examined even with facial swelling.[193,194] Ocular US has been described for intraocular disease, such as retinal detachment (Fig. 196-10), retinal hemorrhage, vitreal hemorrhage , intraocular foreign body, dislocated lens, and retro-orbital hemorrhage.[191,192,195,196] The sensitivity of ocular US for retinal detachment by emergency physicians is 100%, and the specificity is 83 to 92%.[197,198] In addition, the optic nerve sheath diameter can be measured behind the eye, reflecting intracranial pressure.[199-202] The sensitivity of such measurements ranges from 83% in children to 100% in adults.[199,203]

Soft Tissue Ultrasound

Except in the hand and foot, US in soft tissue is straightforward because of the lack of air and bone in the skin and subcutaneous tissue. Soft tissue US is used to differentiate cellulitis from abscess, to detect foreign bodies and hernias, and to evaluate other soft tissue pathologic processes, including masses, pseudoaneurysms, and glands.[204-208] A high-frequency linear transducer moves from normal skin to the abnormal area. Cellulitis or edema will cause an echogenic pattern with cobblestoning between fat lobules (Fig. 196-11). Abscesses are irregular hypoechoic to anechoic collections within the subcutaneous layer but may connect with the surface (Fig. 196-12). US is diagnostic in soft tissue disease for cellulitis, abscess, and necrotizing fasciitis.[150-153,209,210] In the ABSCESS study, clinical examination had a sensitivity of 86% and specificity of 70%, whereas US had a sensitivity of 98% and specificity of 88%.[205] In other studies, use of US changed management for half of adult patients and 22% of children with clinical cellulitis.[206,211] One study showed that incision and drainage is superior to US-guided aspiration in a cohort of patients with soft tissue infection in regard to resolution at 1 week (80% vs. 26%, respectively).[212]

US can differentiate peritonsillar abscess from cellulitis and can be used for guidance of peritonsillar aspiration.[213,214] It can also detect early Ludwig's angina with abscess, dental abscess, epiglottitis, glandular abnormalities, and pseudoaneurysm in soft tissues and fascia of the face.[207,208,215-217] US has also been used in various body areas, including the penis and scrotum, for signs of disruption or infection.[218,219]

Detection of foreign bodies is characterized by variable echogenicity in the tissue with shadowing beneath the foreign body. Metal foreign bodies, such as bullets and intrauterine devices, have characteristically high-reflective echogenicity and ring-down artifacts. Bedside US has variable accuracy for detection of foreign bodies in simulated cases but better accuracy in true clinical

settings.[220-222] Use of a water bath may aid in the detection of superficial foreign bodies.[223]

Musculoskeletal Ultrasound

US has been particularly useful for joint effusion and muscle, tendon, and bone injury. US is excellent for detection of fluid in joints, confirmation of effusions, and guidance of drainage procedures.[29,160,161,224-230] Joint effusions typically are anechoic or echogenic, depending on type and age (Fig. 196-13). Arthrocentesis of both the adult and pediatric hip, in addition to other joints, has been reported with good success.[229,231,232]

Diagnosis of ligamentous injuries and muscle avulsion and hemorrhage has also been reported.[224,233] Muscle and tendon abnormalities are detected by anechoic and heterogeneous abnormalities (Fig. 196-14). Detection is often assisted by movement of the limb. Tendons and their anisotropic longitudinal fibrils can be visualized near joints, with pathologic tears appearing as a discontinuity of the tendon. Muscles are hypoechoic with echogenic borders. Tears and hemorrhage are interruptions of this normal pattern.[224,234,235] Water bath techniques provide a better acoustic window for shallow tissue, such as fingers.[236]

The characteristic reflection of bone with immediate shadowing is used to identify normal bone and its contour. Fractures are seen as a defect in the bony cortex.[46,224,237-240] The image of the cortex can be useful for guidance of fracture reduction.[241-243] Comparison with the contralateral side may also be helpful. Confirmation can be done by US imaging before and after reduction.[244]

US is accurate in the detection of fractures, joint effusions, bursitis, cysts, and hematomas.[140,229,231,245-247] Prospective evaluation of finger fractures demonstrates good accuracy[228] (Fig. 196-15). Other fractures studied include femur, sternal, rib, and forearm fractures.[224,237-240]

Transcranial Doppler Ultrasound

Transcranial Doppler US has been used for detection of abnormal flow patterns in the brain and for detection and treatment of middle cerebral artery strokes. An advanced procedure, typically using a phased array transducer over a bone or orbital window in the skull, color Doppler and spectral Doppler scanning is performed at different levels of intracranial vessels for detection of abnormal patterns.[39]

Testicular Ultrasound

Testicular scanning is an advanced US application that requires visualization of the normal and symptomatic testicle with a high-frequency probe. The testicular structures, including the normal homogeneity of the testicle, are evaluated, and Doppler scanning is performed for evaluation of normal venous and arterial flow (Fig. 196-16). Absent or decreased flow on the affected side indicates possible torsion, whereas increased flow indicates epididymitis. Experienced emergency physicians accurately diagnosed testicular pain with a sensitivity of 95% and specificity of 94% in a study of 36 patients, which included 3 patients with torsion.[248]

Abdominal Bowel Ultrasound

The use of bedside US for evaluation of appendicitis, diverticulitis, and other bowel disease is an area of increasing interest. There has been variable experience with the use of graded compression US to detect appendicitis (>6 mm), with reported sensitivity of 67% and specificity of 92% (Fig. 196-17).[249] Whereas there is considerable effort looking at the use of US first and then computed tomography for appendicitis, the accuracy of emergency physician–performed US for appendicitis has been equivocal.[249-251] In women, endovaginal US can be used to rule out adnexal disease.[98]

The use of US for diverticulitis, intussusception, volvulus, and small bowel obstruction has been reported.[252-254] Thickening of the bowel, dilated bowel with fluid-filled loops, and changes in

www.ketabpezeshki.com 66485457-66963820

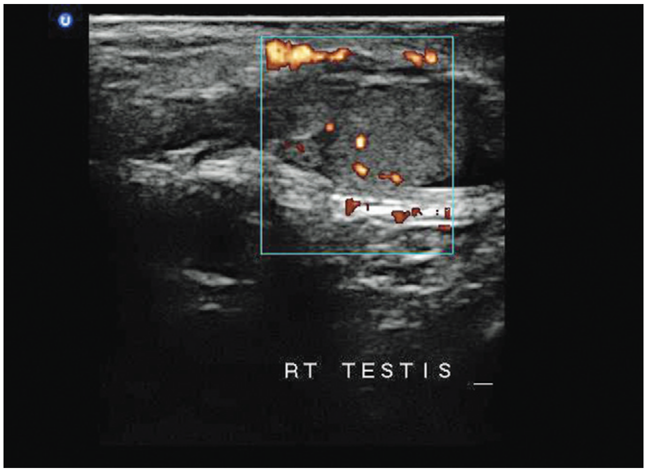

Figure 196-16. Testicular ultrasound examination with normal power Doppler.

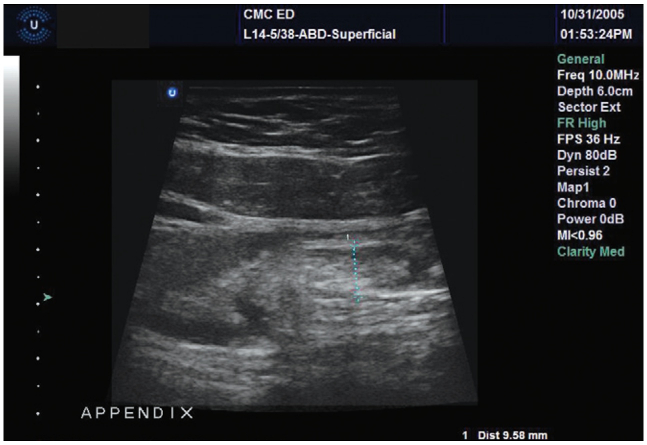

Figure 196-17. Image of noncompressible appendix compatible with appendicitis.

vascularity suggest disease. Tracing of the bowel to normality may also show cutoff points.

Hernias, described in the soft tissue section, may also be detected as masses in the ventral, inguinal, paramedian, femoral, and scrotal areas.[255] Free air, with comet tails and artifacts in areas that are usually normal, such as between the liver and diaphragm, may also be detected in patients with suspected perforated viscus.[256]

Ascites, similar to traumatic free fluid in the sonographic appearance, will be much more apparent with tremendous amounts of free anechoic fluid, small echogenic liver, and outlined organs. Small amounts of ascites may be the first clue to abnormal pathologic states.

Pediatric Emergency Ultrasound

The use of US for children in the ED has two paths, one that mirrors the applications that have been used for adults and a second exploring the more specific pediatric abdominal applications.[257] The use for patient management and accuracy can vary per application.

The FAST examination for evaluation of abdominal trauma in children is specific (98%), but the sensitivity is only 20%, making it difficult to use without further imaging or other testing.[67] In

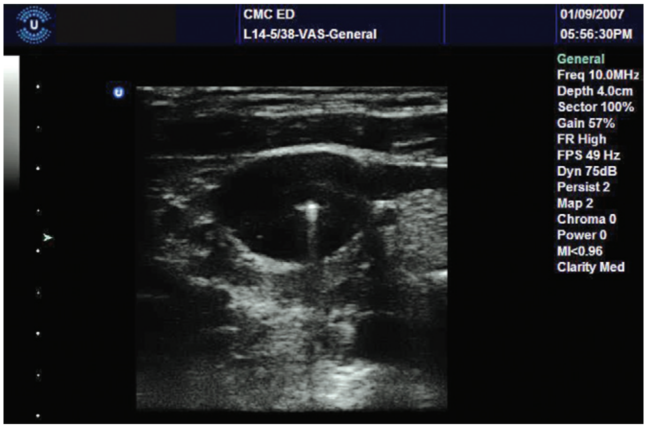

Figure 196-18. Transverse image of internal jugular vein for procedural guidance.

addition, specific pediatric abdominal applications that are common in the radiology suite have begun to be explored. Case reports and case series of intussusception, appendicitis, and pyloric stenosis have been reported.[251,252,258-260]

Ultrasound for Procedural Guidance

In 2001, in response to the Institute of Medicine report *To Err Is Human,* the Agency for Healthcare Research and Quality (AHRQ) sanctioned a report on actions that may improve patient safety.[261,262] The report contains a recommendation for US guidance for internal jugular central line insertion. Since then, the use of US for procedural guidance has expanded for many emergency procedures, especially vascular access, and is advocated for error reduction.[263]

Procedural guidance can be static or dynamic.[264] *Static guidance* suggests that US has been placed over the anatomic area, and the area is marked while angle and distance information is noted. *Dynamic guidance* describes procedures performed with real-time US visualization of the needle entering the anatomic area on the monitor as well as on the patient.

There are two common axis approaches to vein cannulation: transverse, in which the vein appears as a circular structure on the screen; and longitudinal, in which the vein appears as a tubular structure along the width of the screen. In the transverse approach (also known as out of plane), the probe's long axis is centered transverse (90 degrees) to the long axis of the anatomic area, guiding the needle to bisect the probe at its center, which gives centering and depth information (Fig. 196-18). In the longitudinal axis (also known as in-plane), the probe is placed along the long axis of the anatomic area, and the needle is introduced in the long axis of the probe, giving depth and trajectory information (Fig. 196-19). Whereas the short-axis approach is more popular with novices, the long-axis approach may be safer because of the visualization of the needle tip during the entire dynamic procedure.[150] Finally, an oblique axis has been described, essentially approaching the vessels at 45 degrees but visualizing the target vessels and surrounding structures.[265]

The most studied and most advocated use of US procedural guidance is for central line insertion.[266-269] Both the AHRQ and the National Institute for Health and Clinical Excellence have recommended US guidance for central line insertion.[262,270] US guidance for internal jugular central line insertion can be recommended as a safe and best practice.[271]

US permits the physician to assess the internal jugular for overlap with the carotid artery, vessel diameter, and presence of

www.ketabpezeshki.com 66485457-66963820

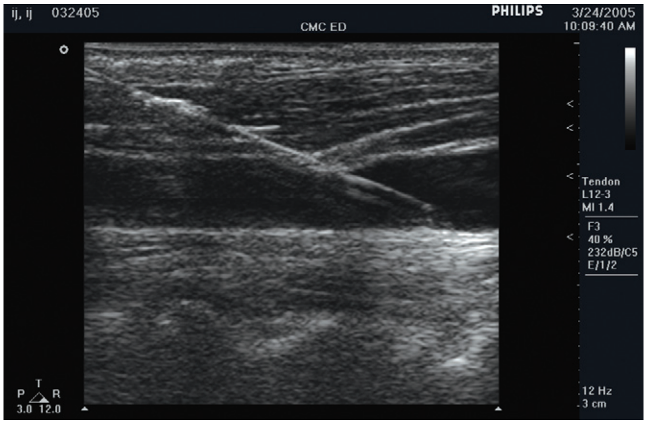

Figure 196-19. Longitudinal image of the needle in an internal jugular vein for procedural guidance.

luminal clot or vessel obliteration.[186] Internal jugular central line insertion has been studied in the ED, intensive care unit, and radiology suite. In the ED, US-guided internal jugular cannulation is associated with decreased time to flashback and improved success in the difficult-stick patient, improved overall success rate and first attempt and overall rates, reduced time to insertion, and reduced complication rate.[268,272,273] The Valsalva maneuver and Trendelenburg position may assist in increasing the size of the cross-sectional area.[274]

US does not prevent posterior vein wall penetration as reported in case reports and simulated models.[275,276] Adverse events (hematoma, arterial cannulation, pneumothorax, and unsuccessful placement) can occur in up to 20% of patients having US-guided internal jugular catheterization.[277-279]

Femoral vein insertion has been studied in cardiac arrest patients, and improved cannulation rate and reduced complications have been reported.[280] Several maneuvers can optimize the success rate of femoral vein cannulation, including the reverse Trendelenburg position and placement of the pressure on the iliac vein proximal to the femoral vein.[188,281,282]

US does not contribute to procedural success in subclavian vein cannulation because of the lack of a convenient window for the subclavian vein under the clavicle. Laterally, toward the junction of the axillary vein and subclavian veins, the vein can be visualized in the chest wall.[283,284] Although it may be cannulated there, the challenge is to insert the catheter through the pliable soft tissue of the anterior-superior chest.[191,284,285] The supraclavicular fossa is a window for central line insertion, and the subclavian and brachiocephalic veins may be imaged at this site.[192,286]

US-guided central access decreases complications and attempts but did not improve success rates in pediatric critical care patients.[287]

Emergency physicians are able to use US to insert peripheral intravenous catheters in patients with difficult access with high success rates.[193-195,288,289] Only one randomized study showed no differences in number of attempts, time to successful catheterization, or patient satisfaction.[290] Veins that are large in width (0.4 cm) or at moderate depth (0.3-1.5 cm) have a higher success rate.[291] Nurses and ED technicians have also been taught to use US for peripheral venous guidance.[292-294]

The use of one operator versus two operators has not been shown to increase success rates.[295] US can facilitate peripheral vascular access by the Seldinger technique.[296] Marking of the skin in its long axis while using the short axis has not increased success rates.[297] Pediatric US-guided intravenous catheter placement in difficult-access pediatric patients has been shown to be more successful than traditional techniques.[298,299] Arterial access, including

radial artery aspiration and cannulation, is more successful with US guidance.[300,301] US has confirmed intravascular location with a combination of B-mode and Doppler mode, in which the needle, guidewire, and catheter can be located by US.[302-304]

Sonographic confirmation of intraosseous placement has also been described with detection of Doppler flow outside the bone and inside the marrow.[305,306] Numerous other procedures using US guidance have been described in emergency practice (Table 196-2).

Torso Drainage Procedures

US can facilitate procedures such as paracentesis, thoracentesis, and pericardiocentesis. It confirms the presence of abnormal fluid, amount, and relative location with anatomic and sonographic windows. It can also locate anatomic structures that may be in the way or define structures for location of the space.

Paracentesis, including US-guided diagnostic peritoneal lavage, has been described. Static or dynamic guidance may assist this procedure by identifying the deepest location of ascitic fluid and obstructing bowel loops (Fig. 196-20). Thoracentesis is assisted by definition of the diaphragm as the most inferior anatomic landmark to avoid solid organ injury. In the left thorax, potential cardiac laceration may be avoided by the use of US. Routine use of sonography has been associated with a reduced rate of

www.ketabpezeshki.com 66485457-66963820

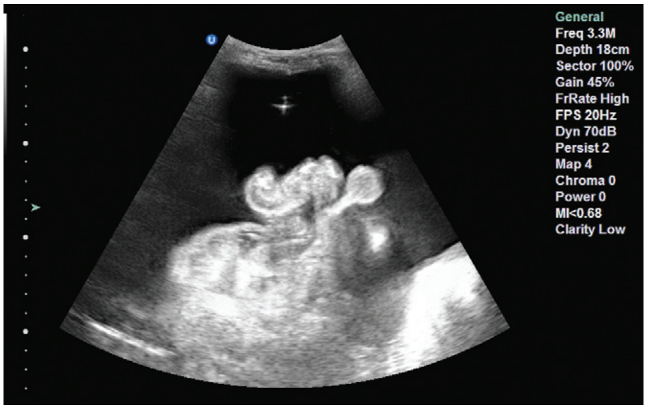

Figure 196-20. Needle entering peritoneum during paracentesis.

Figure 196-21. Needle entering joint space during arthrocentesis.

pneumothorax and tube thoracostomy.[307] Pericardiocentesis also can be facilitated by location of the best window (subcostal, apical, or parasternal long) and needle guidance into the pericardial space, lessening the likelihood of ventricular puncture.

Soft Tissue and Musculoskeletal Procedures

US-guided aspiration of abscesses has been described, but incision and drainage is more effective in treatment of cutaneous soft tissue infections.

Foreign bodies can be identified and removed with the guidance of US. Static guidance marks the location, depth, and size of the foreign body. Dynamic guidance requires an incision remote from the overlying skin to allow the probe to monitor the procedure.

Arthrocentesis and joint injection may be assisted by US to detect effusion, to identify joint landmarks, and to confirm the needle tip in the joint (Fig. 196-21). Use of US reduces the number of attempts and increases the overall success rate in non-knee joints but not in knee joints.[226,231,308] Sonographic needle guidance also improves performance and outcomes in intra-articular joint injections.[309]

US may assist hematoma aspiration and blocks by directing the needle into the site.[310] US-guided fracture reduction, especially in pediatric fractures, has been described with good results.

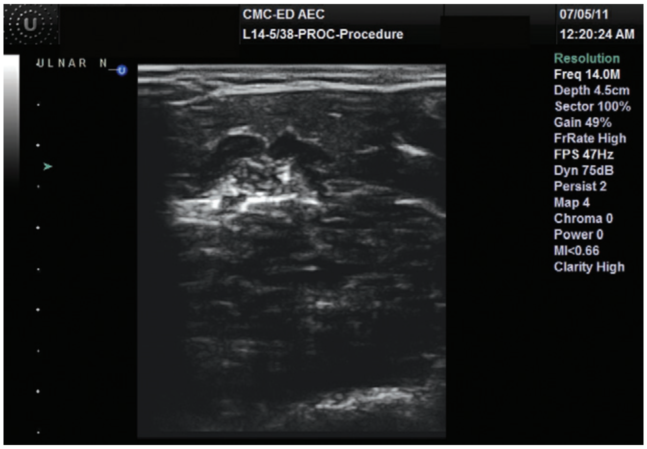

Figure 196-22. Sonographic ulnar nerve block.

Nerve Blocks

US-guided nerve blocks confirm needle placement around the nerve and allow anesthetic to be delivered at sites around the nerve, avoiding fascicular deposition (Fig. 196-22). Multiple US-guided nerve blocks have been described in both the emergency medicine and anesthesia literature, and it is clear that most percutaneous nerve blocks can be performed with assistance of US. US-guided femoral nerve blocks produce a more complete blockade than the landmark or fascial pop techniques.[311] In the setting of knee trauma, femoral nerve blocks appear to reduce pain more effectively than intravenous analgesics.[312,313]

Abdominal Procedures

In addition to paracentesis, described earlier, US-guided hernia reduction, suprapubic cystostomy, and gastrostomy tube placement have been described in the literature. Hernia reduction may be assisted with gentle, constant pressure over the hernia with the probe in the direction of opening through the peritoneum with resultant confirmation that the hernia has been reduced. Suprapubic aspiration and cystostomy are assisted by the detection of a full bladder with secondary guidance of the needle into the bladder for aspiration or removal. US has been touted in a pilot study to guide gastrostomy tube replacement with confirmation.[314]

Lumbar Puncture

Lumbar puncture can be assisted by US by the identification of the spinal processes for sonographic landmarks for placement of the needle in both the transverse and longitudinal plane, even in large patients.[315,316] In addition, foraminal location can be identified, allowing a paramedian approach to lumbar puncture.

Out-of-Hospital Ultrasound: Disasters and Remote Settings

US has been used in the out-of-hospital, military battlefield, disaster, and international medicine settings. The use of US has been described in European and other settings by physicians in the out-of-hospital arena, including ground, helicopter, air, and space,[9,317-323] and by paramedics for FAST and abdominal aorta examinations.[324]

The military forced development of small compact US machines and has been an extensive user of US in combat situations, including the frontline, combat support hospital, and tertiary hospital settings.[9,11,325] US has been used in the Armenian earthquake of

www.ketabpezeshki.com 66485457-66963820

1988, the Haitian earthquake of 2010, and other multiple casualty situations.[326-328]

US interpretation may be enhanced by satellite and telesonography systems that allow remote guidance and interpretation.[329] In remote and international low-resource settings, US has become the imaging test of choice for emergency care.[330,331]

INTEGRATION INTO EMERGENCY MEDICINE PRACTICE

US has been integrated into emergency medicine practice because of the need for effective, noninvasive, nonpainful, portable imaging techniques.[14] US, whether it is introduced in medical school, residency, or clinical practice, is a skill that requires constant attention with hands-on practice and interpretation.[5,332] Emergency US, the performance and interpretation of ultrasonographic examination at the bedside in the emergency setting, has enhanced many aspects of emergency care, making diagnosis and treatment more rapid, efficient, safe, and accurate.

CHAPTER 197

Process Improvement and Patient Safety

Shawna J. Perry, Robert L. Wears, Pat Croskerry, and Marc J. Shapiro

PERSPECTIVE

The overall process of patient care in the emergency department (ED) begins with the initial decision by the patient (or caregiver or family) to seek emergency assistance and ends with the patient's disposition and follow-up. The care process is highly complex, with many separate components, people, and interfaces with other processes in the health care organization (Fig. 197-1). This complexity, among other things, provides many opportunities for process failures, "errors," and adverse outcomes.

Although process failures in health care have been studied for decades, most of that effort originated from outside of the field of health care, with health care professionals largely unaware of it.[1] This began to change in the early 1990s when the Harvard Medical Practice Study reported that almost 4% of hospitalized patients suffered significant adverse events during their care and that almost 30% of these were due to human error.[2] The study noted that failures in ED care accounted for only approximately 3% of all adverse events, but more than 90% of adverse ED events were judged to be preventable. This study and others ultimately led the Institute of Medicine to issue a report in 1999 titled *To Err Is Human: Building a Safer Health System*.[3] This report provoked the interest of the media and the general public and thrust the issue of safety in health care onto the national agenda. The major accomplishment of the Institute of Medicine report was the introduction of some of the fundamental concepts regarding safety in complex systems for the first time into the world of health care. The most transforming concept was the idea that failures (or errors) in care are not the result of bad decisions or bad individuals but are instead intrinsic properties of the processes of care in the health care system. Thus efforts to reduce these failures should be focused on changing the processes of care rather than on identifying, retraining, or punishing the workers.

The response within health care was mixed. Most health care professionals focused on the projected number of deaths due to error, arguing that they were either too high[4,5] or too low,[6] and a third, smaller group argued that the concept of error is essentially contestable and thus an approach aimed at counting errors is fundamentally flawed.[7] The transforming concept of "system failure" rather than "human error" gradually gained acceptance, despite going against the natural human tendency to believe that individuals cause outcomes. This viewpoint is problematic because it undermines a clinician's sense of free agency; health care providers prefer not to view themselves as trapped in a system that is moving inexorably toward a poor outcome.

Within emergency medicine, safety and quality have been addressed by task forces, interest groups, and special sections examining the practice of emergency care, its processes, and environments with tools from the "science of safety" to improve performance and to cultivate patient safety.[8] A basic curriculum for teaching about safety at the undergraduate level was developed, with similar efforts taking place to implement safety concepts into medical education.[9]

Interesting lines of research on the safety and processes within emergency care have been performed, with a number of patient safety case reports published in the emergency medicine literature.[10] Chisholm[11] reported that emergency physicians are interrupted, on average, approximately once every 6 minutes and that two thirds of those interruptions cause a change in task; this is important because both interruptions and task switching frequently lead to process failures. Fordyce[12] reported that self-detected errors occurred in almost 20% of all ED cases but that only 2% were associated with adverse events. Fordyce's work emphasizes that errors are ubiquitous but only rarely combine with other factors to produce adverse events, and it supports the notion that focusing on elimination of errors is not likely to be a productive strategy for improvement.

Coiera[13] studied emergency physicians in Australia and reported high communication loads and found similar levels of interruptions. Morey[14] reported that specific training of emergency physicians and nurses to work together in teams led to reductions in failures and improved performance. Perry and colleagues[15,16] identified a number of unexpected yet highly consequential failures of information technology that were difficult to detect, some occurring during emergency resuscitations. Wears and Perry[17] noted ergonomic shortcomings in the workplace and pointed out their potential to contribute to failures in care. Hall[18] identified significant delays related to ED layout, with time to assessment of chest pain patients being longer for patients placed behind a door or who were 25 feet or farther away from the physicians assigned to care. These examples of safety research in emergency care demonstrate the wide range of known and unknown contributors to patient safety and the importance of the work processes that overlay this complex work environment.

SOURCES OF FAILURE IN EMERGENCY CARE

Many characteristics of emergency medical practice make it vulnerable to failures (Table 197-1).[19-26] This section focuses on some of the principal factors that contribute to adverse outcomes and how they might be better managed to improve safety.

Emergency Department Design, Human Factors, and Ergonomics

Two frequently overlooked contributors to lowered safety in any work environment are the design of the workspace and the

www.ketabpezeshki.com 66485457-66963820

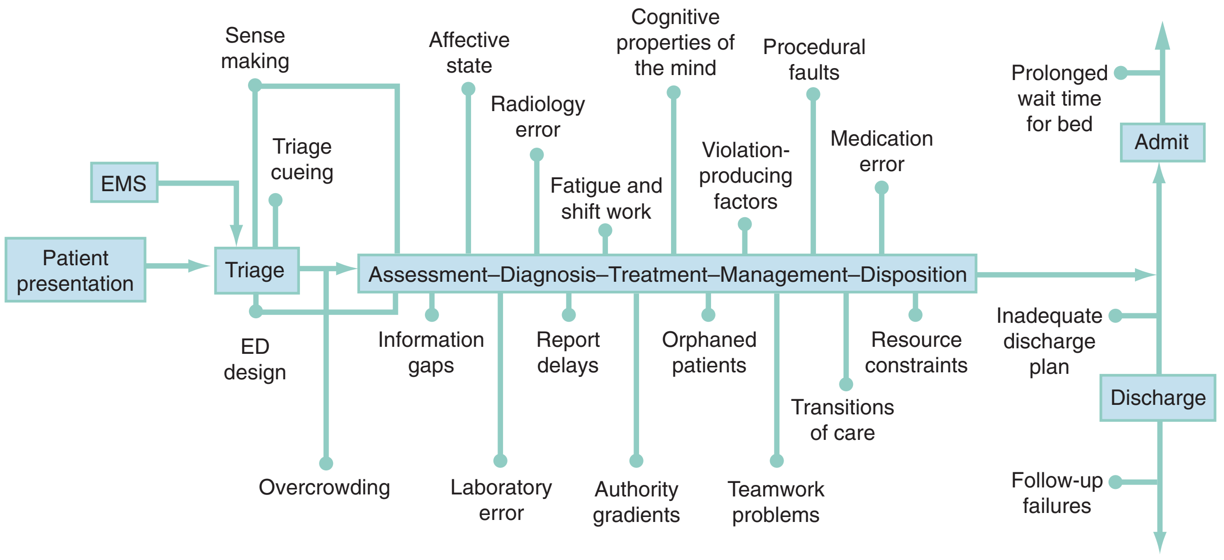

Figure 197-1. Process mapping showing sources of failures. The overall process is highly simplified and presented as a linear model of a patient's trajectory. (The actual process is much more complex, involving multiple simultaneous patients at different stages and loops within a given patient's trajectory.) Sources of failure may occur in parallel or at multiple stages in the sequence and are often additive in their overall effect on patient safety.

Table 197-1 Characteristics of the Emergency Department That Affect Performance

INTRINSIC*	EXTRINSIC†
Limitations of human cognition	High communication load
High levels of uncertainty	Poor teamwork
High decision density	Overcrowding
High cognitive load	Production pressures
Narrow windows of opportunity	High ambient noise levels
Multiple interruptions or distractions	Information gaps
Low signal-to-noise ratio‡	Report delays
Surge phenomena§	Inadequate staffing
Novel or infrequently occurring conditions	Poor feedback
Patient factors (e.g., acuity, language, delirium)	Inexperience
	Inadequate supervision
	Sleep deprivation or sleep debt
	Fatigue
	Multiple transitions of care
	Poorly designed procedures
	Emergency department layout

*Intrinsic factors are intimately part of the nature of emergency care and as such are not amenable to change but instead must be compensated for.
†Extrinsic factors are in principle manageable and typically relate to resource constraints.
‡Low signal-to-noise ratio refers to the low likelihood of a critical diagnosis compared with a benign diagnosis for similarly presenting symptoms and findings (e.g., subarachnoid hemorrhage vs. tension headache).
§Surge phenomena are the rapid changes in volume and acuity routinely experienced in many emergency departments.

engineering of the tools, technology, and procedures used to perform the work.[27] This is especially true for EDs because the majority were not designed for the care actually being delivered there.[28] ED caregivers are required to adapt to the space by creating "work-arounds" to cope with the limitations and impediments of the workspace.

Consistency is rarely found in equipment across or between areas. For instance, the blood pressure monitor in the ED is often not the same type or model as that used in the radiology department when the patient goes for diagnostic tests. In addition, tools and technology are seldom developed or assessed for their "user-centered design" or ability to be integrated into existing workspace and the associated hazards for doing so. This is most apparent with regard to health information technology, which is often introduced for improvement of safety and quality; however, embedded latent features that can produce clinical failures that are "hard to see" have been demonstrated.[29,30] Study of computerized physician order entry by Koppel[31] showed that the software facilitated 22 types of medication error risks, for example, displays that prevented a coherent view of the patients' medications and inflexible ordering formats that generated wrong orders. Other contributors to information technology failure within health care are the lack of usability testing,[32] delays in in-service training, and failure to reassess the impact of the new technology and changes in clinical work after implementation.[33]

The contribution of poor design to the difficulty in maintaining safety in a health care environment is generally overlooked by staff members, who cope with these difficulties as "part of the job."[17] Vigilance is the common solution but despite caregivers' best efforts cannot be sustained, given competing demands for their attention. This increases the risk of a failure's not being recognized as linked to the workplace, the procedures, or the equipment, despite being "tightly coupled" to any or all of these.

Overcrowding

ED crowding has long been recognized as a major source of time-delay failures and a threat to patient safety.[34,35] Such delays are not simply an inconvenience to the patient but may give rise to significant adverse events. For example, patients with atypical presentations of severe illness who have been mis-triaged to low levels of acuity may experience inordinate and, occasionally, fatal delays. In other cases, such as community-acquired pneumonia, cellulitis, and lacerations, more expedient care may significantly improve the outcome of the illness. A significant proportion of patients who leave the ED without being seen may have serious illness and incur delays in diagnosis and treatment. At the other end of the process, when the patient is ready for admission to the hospital from the ED, further time-delay errors may occur (see Fig. 197-1). Not only do such delays create throughput problems for the ED and contribute to overcrowding by front-end loading or "entry block," but they also give rise to discontinuities in care and may lead to adverse events that are difficult to identify because they are manifested once the patient has left the ED.[36-39] Manifestations of

www.ketabpezeshki.com 66485457-66963820

cognitive overload associated with ED overcrowding are diminished overall with increased use of heuristics (mental shortcuts) in medical decision-making and more biased and risk-laden decisions.

Information Gaps

Missing information is common in emergency care and can significantly affect quality of care.[40] Hospital records, especially discharge summaries, details of past medical history, and other important information, are often difficult to access in an expedient manner, even with electronic medical records. Referral notes sent by family physicians with the patient may not reach the emergency physician or may not contain relevant or significant details. In these situations, emergency physicians make clinical decisions and take action on the basis of incomplete, limited, or erroneous information. Emergency clinicians often end up not seeking additional or clarifying information because of time pressures, patient volume, or limited methods to obtain more information (e.g., the referring physician's office is closed), essentially accommodating to this "gap" in continuity of care and the associated increase in patient risk.[41]

Box 197-1 Violation-Producing Factors

- Gender
- Mood
- Ill health
- Risk seeking or risk aversion
- Normalization of deviance
- Maladaptive group pressures (groupthink)
- Maladaptive copying behavior
- Underconfidence or overconfidence
- Perceived authorization to deviate
- Authority gradient effects (obeying authority figure or absence of disapproving authority figure)
- Likelihood of detection

Based on an original schema by Williams JC: Assessing and reducing the likelihood of violation behavior—preliminary investigation. Proceedings of an International Conference on the Commercial and Operations Benefits of Probabilistic Safety Assessment. Edinburgh, Institute of Nuclear Engineers, 1997. Modified for emergency medicine in Croskerry PG, Wears RL: Safety in emergency medicine. In: Markovchick V, Pons P (eds): Emergency Medicine Secrets, 3rd ed. Philadelphia, Hanley & Belfus, 2003. A summary can also be found in Reason J: Managing the Risks of Organizational Accidents. Aldershot, UK, Ashgate, 1997.

Performance-Shaping Factors

Blaming individuals for errors contributes little to an understanding of risk, vulnerability, and failure. A wide variety of ambient, systemic conditions in the ED contribute to the majority of adverse events and near misses that occur (see Table 197-1). Some performance-shaping factors can be considered to be "intrinsic," part and parcel of the milieu of emergency medicine and thus not amenable to direct control (e.g., cognitive workload, multiple distractions and interruptions, and high acuity). These factors must be managed by strategies to buffer or to mitigate their effects. In contrast, other "extrinsic" performance-shaping factors typically reflect limitations of resources (e.g., staffing ratios, production pressure, and ED layout). When resources are limited, a tradeoff can occur in the ability of the ED to provide safety and quality in patient care. This condition is referred to as RACQITO (*r*esource *a*vailability *c*ontinuous *q*uality *i*mprovement *t*rade-*o*ff),[42] a concept derived from speed-accuracy tradeoffs described in industrial settings.

Violation-Producing Factors

Although at first one might think that violations of organizational policies, rules, and procedures would always be causes of failures and adverse events, the modern approach to safety has pointed out that some violations are actually necessary for the safe functioning of the system, and others fall somewhere in between.[43] Aside from recklessness, drug use on the job, moral failings, and other egregious acts, research in other domains has identified other factors that are associated with the occurrence of rule and safety violations (Box 197-1). The "normalization of deviance"[44] is an accumulated tolerance of small variances from safe operating conditions that develops over time, ultimately compromising safety. This is evidenced in overtaxed EDs coping with overcrowding of patients (e.g., performing evaluation and management of patients in hallways). Violations can also occur in response to perceptions of authority. They may occur through a directive supporting violation from an authority figure (e.g., nursing supervisors order admitted patients moved to inpatient beds without calling to report if there are delays in reaching inpatient nurses), the absence of a disapproving authority (e.g., physicians leaving shifts early and the medical director does not address the behavior), or an individual's self-perception that he or she is authorized to disregard or to deviate from prescribed procedures (e.g., ED electrocardiograms done on patients in chairs because there are no available stretchers).

Fluctuations in mood can also contribute to violations for a variety of reasons and will result in inconsistent clinical performance; men are more likely to break safety rules and to engage in more risk-taking behavior than women are.[43] Risk-seeking and risk-averse attitudes are associated aspects of decision-making in the ED.[45]

Teamwork

Good teamwork is essential to the safe practice of emergency medicine, but emergency caregivers are not trained or evaluated as teams. Teamwork training in other fields, such as aviation, has been successful in reducing failures related to poor communication, cross-monitoring (observing others' behaviors to reduce risk of failure and share workload), and authority gradients (both within and between professions).[46] Work on transferring teamwork training principles to emergency medicine suggested that teamwork failures are involved in approximately 40% of malpractice cases.[47] The lack of cross-monitoring across team members and the failure of advocacy or assertion on behalf of the patient by caregivers to avoid patient harm were two of the factors most frequently identified. A multidisciplinary teamwork training course implemented in nine EDs showed a significant improvement in quality of team behaviors and a sixfold decrease in observed clinical errors.[14] Teamwork is not a specific fix for any one type of error, but it should be viewed as one type of adaptable human factor intervention with a set of teachable skills and behaviors capable of increasing system resilience and safety, which are hallmarks of high-reliability organizations.[48]

Teamwork training requires a change of culture, which can be difficult for ED staff. Institutional and ED leadership must be fully committed to the process before implementation of teamwork training for all staff. Resistance to behavioral change is likely to be encountered, and it will be necessary to demonstrate the clinical relevance of this training. High-fidelity medical simulation supported by audiovisual feedback offers the educational methodology to help clinicians and staff understand the necessity of behavioral change.[49] A major unanswered question is how to embed teamwork behaviors into medical training and how to sustain the behaviors over time.

www.ketabpezeshki.com 66485457-66963820

Authority Gradients

Almost all human groups have some form of authority gradient among members. This hierarchy can be based on profession (e.g., physicians have greater authority than nurses) or organizational rank (e.g., attending physicians have more authority than residents). Ideally, information between team members should flow freely, but this may not occur if low-authority members are inhibited by differences in seniority, stature, expertise, profession, or social status. There are clear examples of cases in which authority gradients have been responsible for adverse events.[50] A work environment in which all team members feel comfortable expressing their viewpoint, especially if it is a dissenting one, requires cultural change that can begin with the physicians who occupy the highest authority position in the clinical setting. Authority figures have the ability to initiate change by recognizing the value of perspectives other than their own and eliciting them from other clinicians and staff (e.g., asking a patient's nurse what he or she thinks may be going on with the patient). Senior clinicians are in a powerful position to bridge gradients by fostering open communication through multidisciplinary rounds, demonstrating that they are approachable (e.g., acknowledging staff by name), and using clinical narratives from their own experience that illustrate near misses and judgment failures.[51]

Cognitive and Affective Limitations

The human mind has characteristic dispositions to respond to particular stimuli and contexts in specific ways. A great deal of effort has gone into identifying and describing these; more than 50 *cognitive dispositions to respond* have been described.[17,52-54] A number of strategies have been proposed to reduce the adverse outcomes associated with cognitive dispositions to respond.[55]

The overall process of patient care in the ED is driven by a process of making clinical sense out of multiple sets of fragmented, tangential, and interrupted stimuli. This is aimed at making an accurate diagnosis if possible or, more commonly, a useful framing of the problem, which can determine management and disposition. Although many diagnoses, such as lacerations, dislocations, fractures, and foreign bodies, are self-evident, others (e.g., chest pain, fever, headache, abdominal pain, and syncope) are often associated with high levels of diagnostic uncertainty and are more likely to lead to problems. Cognitive biases can frequently be identified in retrospect after diagnostic failures,[56] but the problem of hindsight bias makes this identification problematic.[57]

In addition to cognitive mental properties, the emotional state of the physician can affect his or her decision-making; this has been referred to as *visceral bias*.[17,53] Relatively little attention has been directed to the important role of affective bias in decision-making. Although processes such as countertransference, fundamental attribution error,[42] and the economy of perception that underlies stereotyping are well understood in psychology, health care workers are typically less aware of them (e.g., "She's a drug seeker," "He's a frequent flyer," and "She just wants attention") and their effect on clinical interactions.[58]

Fatigue and Shift Work

Both fatigue and shift work contribute to performance failures,[59] but relatively little research has been directed to their respective impacts on clinical performance in the unique milieu of the ED.[60] Although the two are often considered together, they are different entities and exert both qualitatively and quantitatively different effects on performance.[61] Fatigue has a number of determinants separate from those associated with shift work (Fig. 197-2).

Shift work has extensive, well-documented, detrimental effects on health that in turn have an impact on well-being and job performance.[62] Importantly, it leads to disruption of circadian rhythms that inevitably result in sleep deprivation. Circadian dyssynchronicity largely occurs through missing sleep in the *anchor period,* approximately midway through the sleep phase when core temperature and arousal level are at their lowest. It has been stated that the performance degradation of someone who has been up all night is roughly equal to that of a person with a blood alcohol level of 0.1% (Box 197-2).[63]

The acute effects of sleep deprivation are well known, but the chronic effects are less appreciated. Invariably, working a night shift results in less sleep the following day, and subsequent sleep is often disrupted and fragmented in the struggle to restore the circadian rhythm before the night-shift cycle repeats itself. This results in the accumulation of a *sleep debt* that has a significant impact on performance. A study of anesthesia residents on a normal work schedule, with no on-call duty in the preceding 48 hours, showed daytime sleepiness scores comparable to those of patients with narcolepsy or sleep apnea.[64] The on-call schedule of these subjects (five periods per month) entailed considerably less sleep deprivation and fragmentation than an average emergency

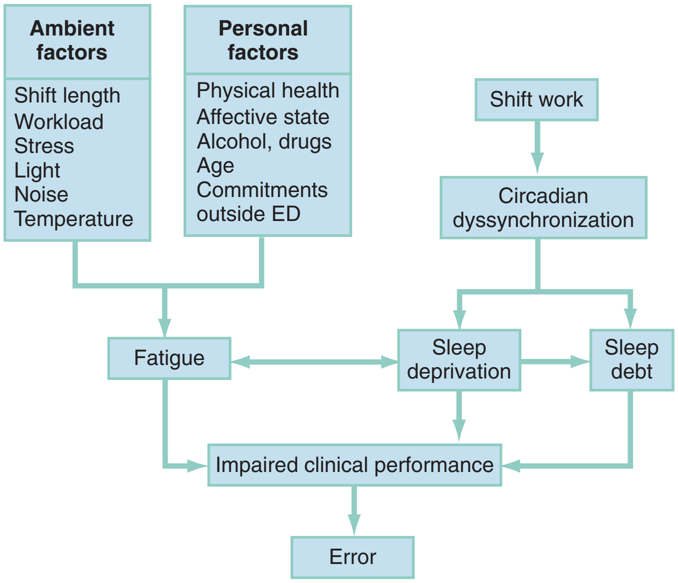

Figure 197-2. Relationships between shift work, fatigue, and performance.

Box 197-2 Effects of Sleep Deprivation

Longer reaction time
Lapses in attention or concentration
Lost information
Errors of omission
Poor short-term memory
Poor mood (increased confusion, stress, and irritability)
Reduced motivation
Distractibility
Sleepiness
Poor psychomotor performance
- At circadian low points
- When sedentary
- On long, difficult, or externally paced tasks with no feedback
- In unchanging surroundings, particularly with reduced light or sound, or with low motivation, interest, or novelty

Modified from Bonnet MH: Sleep deprivation. In: Kryger M, Roth T, Dement WC (eds): Principles and Practice of Sleep Medicine. Philadelphia: WB Saunders; 2000:53-71.

www.ketabpezeshki.com 66485457-66963820

physician's schedule. Increasing age is associated with decreased tolerance for sleep deprivation.[65]

Performance declines as work hours increase,[66] but the optimal shift length in the ED is unknown and difficult to delineate for several reasons. The relationship with workload or acuity is not well appreciated, and some workers exhibit contradictory incentives, such as preferring to work longer shifts to get more days off. More recovery time between shifts might be expected to enhance job performance, but these issues remain relatively unexplored. A survey of emergency physicians found a preference for 8-hour over 12-hour shifts,[67] but it is not known whether job satisfaction in the ED translates into improved clinical performance and fewer adverse events. Other ambient conditions within the ED, competing commitments outside the ED, age, ill health, and other factors contribute to fatigue, with evidence pointing toward additional health implications for emergency physicians.[68,69]

The appropriate management of shift work and fatigue to improve patient safety is not well understood, and further research is needed in this area. In most high-hazard industries, the assumption is that fatigue and long, aberrant work hours lead to poor performance; however, in the health care industry, concerns about discontinuity of care and difficulties in changing medical culture have obscured these issues. Given that medical personnel, like all human beings, function suboptimally when they are fatigued, efforts to reduce fatigue and sleepiness should be undertaken, and the burden of proof should be in the hands of the advocates of the current system to demonstrate that it is safe.[63] In the meantime, shift scheduling should be optimized to reduce the impact of circadian disruption, and ED personnel should practice good sleep hygiene. Some basic approaches are listed in Box 197-3.[62,66]

Box 197-3 Rational Approaches to Shift Work

- Optimize circadian-friendly schedules
  - Forward rotating (clockwise with circadian rhythms)
  - Rapid changes
  - Minimize consecutive nights (one or two)
  - 24-48 hours off after nights
  - Allow social time, including some weekends
  - 8-hour shifts (absolute maximum 12 hours)
  - Institute regular, predictable template
- Practice proper sleep hygiene
  - Use a sleep-friendly room: room-darkening blinds, "white noise" (e.g., electric fan) or earplugs, no phones, family aware
  - Maintain a regular sleep routine
  - Try anchor sleep
  - Avoid caffeine, alcohol, and drugs
  - Prophylactic naps
- Modulate circadian rhythms
  - Exercise
  - Consider bright light
- Eat healthy
  - Eat a balanced diet
  - Avoid junk food
  - Keep regular mealtimes
- Promote a healthy lifestyle and work style
  - Promote a personal healthy lifestyle
  - Educate friends and family about shift work issues
  - Educate colleagues about shift work issues
  - Advocate for department improvements in working conditions
  - Advocate for shift worker–friendly community services
- Avoid pharmaceuticals
  - Use caffeine in moderation, prn
  - Do not use sedatives or stimulants
  - Avoid alcohol before sleep

Evidence Report/Technology Assessment No. 43, AHRQ publication 01-E058. Rockville, Md, Agency for Healthcare Research and Quality, 2001; and Frank JR, Ovens H: Shiftwork and emergency medicine practice. CJEM 4:421, 2002.

PROBLEM AREAS IN EMERGENCY CARE

The mechanisms of failure within the ED are remarkably variable, with a cadre of known and unknown contributors. Areas of consistent concern include triage, technical procedures, laboratory and radiographic tests, transitions in patient care, orphaned patients, and medications.

Triage

Triage, or sorting by acuity, is by definition an abbreviated decision-making process that can never be completely safe because of the limited information available, the lack of time invested, and the variety of presentations of illness and injury. Also, there is a low "signal-to-noise" ratio for a number of serious conditions (i.e., when the incidence of a serious condition is far exceeded by that for a benign condition, but their clinical presentations are similar). Inevitably, the triage process involves tradeoffs between sensitivity and specificity. Undertriage for a particular patient would have a greater potential for an adverse event than overtriage, whereas overtriage affects resource utilization and may have an impact on the care of other patients.

Triage assessments are important contributors to process failures and adverse events. Beyond treatment delays, which can occur with undertriage or be produced by overtriage, an incorrect assessment may be the triggering event that initiates a chain of failures. Geography can become destiny, and an inappropriate triage to a specific treatment area may create a bias in the minds of the treating clinicians and staff. The use of five-level triage systems for adults and children, with excellent inter-rater reliability, offers an opportunity to reduce the risk associated with undertriage.[70,71]

Technical Procedures

The practice of emergency medicine requires proficiency in a wide range of procedures with varying degrees of difficulty. Patients who require procedures are at greater risk for adverse events.[12] Contributors to this higher risk include not only problems with proficiency but also a low frequency for use of higher risk procedures. Critical procedures, such as cricothyrotomy, pericardiocentesis, and endotracheal intubation, are rarely performed in many EDs. When they are needed, they are highly consequential events under significant time pressure for intervention, therein reducing opportunity to refresh skills before the procedure is performed. An important challenge in emergency medicine is the acquisition and especially the maintenance of a requisite level of skill. Simulation techniques have considerable potential here[72] but require both capital and human investment to be effective.

Laboratory

The interface between the ED and its ancillary services is critically important. Failures can occur at three phases of laboratory processes. Preanalytic errors mostly occur through inappropriate collection of specimens because of lapses in technique, timing, and identification of both patient and specimen. Analytic errors refer to those that arise directly from the testing process. Postanalytic errors occur after the test result has been obtained and can take

www.ketabpezeshki.com 66485457-66963820

many forms (e.g., keyboard entry errors, overlooked or lost data, and failure of results to reach the physician). Studies of a blood bank and a stat laboratory found that the majority of failures occurred in the preanalytic and postanalytic stages, with less than 5% in the analytic stage.[73,74] Overall, the laboratory defect rate is less than 1%, but the number of exposures is large. Of the failures that do occur, up to 50% may have a moderate impact and up to 8% a severe impact on patient care.[75]

Radiology

Radiographic imaging is a critical aspect of diagnosis and management in the ED. Although patient identification and wrong-side problems are important sources of failure, the majority lie in interpretation. Assuming the radiologist's interpretation to be the criterion standard, the rate of errors in interpretation by emergency physicians and residents may be as high as 16% for plain radiographs and more than double that rate for computed tomography scans.[76] Clearly, not all misinterpretations are consequential, and emergency physicians typically seek the advice of the radiologist when they recognize difficult interpretations. The introduction of digital imaging and picture archiving communications systems has resulted in new patient safety issues related to usability, the effect of monitor resolution on interpretation, and reconciliation of ED physician and radiology readings.[77] Significant interpretation errors can be detected with prompt review of all films by the emergency physician and radiologist, but effective procedures are required to ensure that timely and appropriate feedback and review occur. This approach has been demonstrated to substantially reduce the rate of clinically important misinterpretations.[78]

Transitions in Patient Care

The need for 24-hour access to care and the fragmented nature of health care delivery require the occurrence of transitions of care between providers, either within the ED (at shift changes) or between the ED and other care areas (when patients are admitted, transferred, or discharged). The shift "sign-over" or "handoff" is generally thought of as a communication activity performed for the transfer of clinical information, but it also embodies the transfer of responsibility and authority from one provider to another. The sign-over also conveys general situational awareness (e.g., the state of the department, hospital, and city) and provides a forum for review of decision-making and treatment plans.

There has been little study of these transitions of care, despite their ubiquity and importance to the specialty.[20,79] Sign-overs are highly variable in their content, the number of individuals involved, the physical configuration (e.g., walking, stationary, and at bedside), the tools used to facilitate the transition (e.g., white boards, medical records, and written notes), and the length of the transition process. Although widely regarded as providing a major contribution to adverse events, sign-overs also provide an opportunity for review of decision-making by clinicians and may provide opportunities for recovery by bringing "fresh eyes" to a patient's case.[20,79]

Potential threats to high-quality transitions include the following:

- Interruptions during the turnover (e.g., phone calls and sidebar conversations) can cause a loss of focus and lead to the omission of important information.
- Lack of consistent structure to the turnover: Although the traditional case presentation narrative is generally followed (chief complaint, history, physical examination, initial laboratory results, impression, and plan), the case presentation format does not automatically remind participants of pending or as yet uncompleted tasks.
- Patients are commonly "marked" in ways that can sometimes be helpful but sometimes harmful, especially for at-risk groups such as the homeless, psychiatric patients, alcoholics, and drug abusers.

Common sense and well-meaning approaches such as standardizing verbal content and compulsory use of sign-over checklists risk extinguishing latent safety features inherent to them without further research of this complex and vital work tool for emergency medicine and health care overall.

Orphaned Patients

Orphaned patients are those who have suffered temporary loss or diminished supervision or accountability for their ED care. This may occur at several stages in the process. Patients who are seen and assessed at triage and then wait in the waiting area are temporarily orphaned. Those who are brought in by paramedics sometimes remain on stretchers for hours before being admitted to the ED. Patients who leave without being seen or before treatment is completed have "orphaned" themselves. Patients can also be temporarily orphaned out of the ED for radiographic studies or other special tests. On occasion, patients get "lost in the shuffle" and are overlooked at shift change, or they may get "lost" after one or more consultations with other services. With prolonged wait times, occult conditions can mature to serious and potentially catastrophic levels. A significant cause of orphaning in some EDs is the "boarding" of admitted patients because no inpatient beds are available. In such cases, patients may be put in holding areas in or adjacent to the ED and receive sporadic care from a succession of caregivers who know increasingly less about their conditions. The risk of harm to patients caught in this "gap" within the ED is not well studied.[41,80]

Medications

Medication errors constitute the largest proportion of failures in most general studies, with failures occurring in all six steps of the process (prescription, transcription, dispensing, administration, monitoring, and discharge).[81] Many EDs take on the dispensing role, obviating input from the pharmacy, where many errors are corrected. In addition, team communication errors can contribute to many failures: missed medications, wrong medications, and duplicate dosing. Pediatric patients are at higher risk; drug errors are no more common than in adults, but they are typically more serious.[82,83]

The presence of a pharmacist on the clinical team has been shown to reduce medication errors in several settings.[84] There is great interest in the potential for computer technologies, such as bar coding and computerized physician order entry, to enhance medication safety. However, despite some successful demonstrations, widespread implementation has not occurred, and there is evidence that such systems introduce new problems to replace old ones.[85] The Institute for Safe Medication Practices has recommended that certain problem practices be avoided in writing orders or prescriptions.[86] Success in this area will require more than just individual attentiveness; nurses, unit secretaries, and pharmacists will have to feel comfortable challenging improper use by physicians.

CONCLUSION

The safe management of patients in the ED depends on a multiplicity of processes. All appear vulnerable to failure, yet all have the potential for improvement through judicious process management. Efforts by front-line workers will not be sufficient, and so considerable effort will be required at the administrative or "blunt end" of the system.[87]

www.ketabpezeshki.com 66485457-66963820

Safety in complex dynamic environments, such as the ED, is itself dynamic. *Safety is a "nonevent" because it is evidenced by the absence of things that should not or do not occur,* such as administration of a medication to the wrong patient. It cannot be banked for future use but is created by workers in a well-designed and supportive organizational environment. Achieving safe performance in settings such as the ED is analogous to fighting a guerilla war: there are no dramatic victories, but there are occasional horrific defeats, with no end in sight. The establishment and maintenance of successful safety cultures within health care will require constancy of purpose by health care organizations, willingness to adopt new ideas and tools from outside of health care, and commitment to continued effort and investment.

E. Emergency Department Guidelines

F. Prevention of Street Gang Violence

KEY CONCEPTS

- Youths are particularly vulnerable to and disproportionately affected by violence.
- Physical, verbal, and relational violence in schools is common.
- Media violence, drugs and alcohol, and access to firearms have been associated with increased youth violence.
- Street gangs continue to be a major source of youth violence.
- Involvement of health care providers in youth violence prevention is effective and should occur in the emergency department.

Youth, Violence, and Street Gangs

Jared Strote and H. Range Hutson

PERSPECTIVE

Presently, there are approximately 84 million children and adolescents younger than 20 years in the United States, and this population is increasingly composed of older adolescents and ethnic minorities.[1] The young are particularly vulnerable to violence and injury because of developmental issues, including independence and autonomy, curiosity leading to experimentation (e.g., alcohol, drugs, sex), peer group pressure, immaturity, impulsivity, the feeling of invincibility, narcissism, and developing self-identity.[2] Other factors that increase the vulnerability of youth to violence include the breakdown of family and community structure, media violence, and easy accessibility to lethal weapons (e.g., firearms).[3] Because of these and other factors, violence disproportionately affects children, adolescents, and young adults; and although violent crime has decreased during the last 40 years, youth continue to have the highest rates of victimization.[4] In 2009, almost 500,000 children and adolescents received medical care for nonfatal violent injuries, of which 6% required hospitalization.[5] Homicide is the second leading cause of death for young people and the leading cause of death for young African Americans.[6]

Historically, injuries were incorrectly called "accidents" because they were seen as unpredictable and uncontrollable. Epidemiologic research now shows that injuries, like other diseases, occur in highly predictable patterns and are often preventable and that contrary to popular belief, violence is a learned and predictable behavior.[7] A child's initial exposure to violence usually occurs in the home (e.g., intimate partner violence, child abuse, elder abuse, corporal punishment) and can increase an adolescent's predisposition to violence. The degree to which adolescents are exposed to violence in the home, community, school, media, sports, and peer groups and the extent to which they are victims of violence are associated with their becoming violent themselves.[8-10]

VIOLENCE IN SCHOOLS

More than 600,000 violent crimes occur in schools each year, and more crimes are committed against children aged 12 to 18 years in school than away from school.[11] It is not surprising that many adolescents report a great fear of school violence. In one national survey, 5% of students missed school because of feeling unsafe at school, and 5.6% had carried a weapon to school in the preceding 30 days. The study also noted that 11.1% of students had been in a physical fight on school property and 7.7% had been threatened or injured with a weapon in the preceding 12 months.[6] Notably, 23% of students reported gang activity at their schools. In addition, 7% of teachers are threatened with violence and 4% are physically attacked each year.[11]

Although violence is common in schools, less than 1% of homicides occur in this setting.[12,13] Of these, half occur during transitions in the school day (beginning of school, lunch period, end of school day). Of school-associated homicides, 65% are from firearms, 27% are from stabbing or cutting, and 12% are from beating.[13] Most firearms used in school-related deaths are from the perpetrator's home.[12]

Bullying is increasingly recognized as an important part of school-related violence. Bullying is repeated and intentional intimidation, harassment, physical harm, or some combination of these actions directed at an individual or a group considered less powerful. Up to 54% of students report being bullied on school property within the last year.[14,15] Bullying is further categorized as verbal, physical, or relational (e.g., social exclusion) and direct or technology assisted (cyberbullying). Bullying is associated with higher rates of weapon carrying and use, fighting serious enough to result in injury,[16,17] self-inflicted and accidental injury, hurting of animals, frequent absence from school,[18] drug use,[19] adult criminality,[20] suicide,[21] depression, anxiety, and conduct disorder.[22] Cyberbullying has been growing rapidly in recent years. It is different from traditional bullying in that it can be done anonymously, does not require a power differential, and occurs remotely, away from supervision or exposure to the victim's response.[23]

MEDIA VIOLENCE AND ITS EFFECT ON CHILDREN AND ADOLESCENTS

Children and adolescents are exposed to large amounts of media violence in movies, video games, youth-oriented music, the Internet, and television. By the time Americans reach the age of 70 years, they will have spent up to 10 years watching television.[24] Violence is present in up to 60% of television programs,[25] and Saturday morning children's programming contains up to 25 violent acts per hour, exposing a group that cannot consistently discriminate between real life and fantasy in entertainment. Through television and other forms of media violence, children and adolescents learn and imitate violent behavior, particularly if the aggressor is the hero or the heroine.[24,26] The more realistic the violence portrayed, the greater the probability the violence will be imitated by children and adolescents. Of young men incarcerated for violent crimes (e.g., homicide, rape, and assault), 22 to 34% consciously imitated crimes learned from television. In the media, violence is a quick, effective ending for disagreements and ignores the importance of patience, negotiation, and compromise in resolving conflicts and disagreements. Furthermore, media violence does not portray the true physical and psychological consequences of violent acts. This may lead children and adolescents to

www.ketabpezeshki.com 66485457-66963820

accept violence as a normal way of life, desensitizing them to future acts of violence and making them less likely to intervene when violent acts occur.[27]

Short-term effects of viewing media violence include priming, arousal, and mimicry; long-term effects include desensitization to violence and its outcomes as well as socialization of violent behavior. Mediators of these effects include justification for the behavior and consequences of aggression, perceptions of realism and identification with aggressive characters, age, gender, aggressiveness and intelligence of viewer, socioeconomic status, and parental influence.[25,28]

Media violence is consistently associated with significant increases in aggressive and criminal behavior.[29] The most important factors are the amount of violence viewed, the identification with violent characters, and the perception that television violence is real.[30,31] On television, as much as one fourth of all violent scenes involve use of a handgun.[32] Forty percent of top-grossing movies rated for "general audience" and "parental guidance suggested" feature at least one character carrying a firearm.[33] Popular music and music videos increasingly involve violence, and recent research suggests a link between music and increased violent behavior.[34]

Video games are also connected to youth violence. Video game use is common; game consoles are present in 83% of homes and used almost an hour per day.[25] Labeling of video games can be deceptive, leading to limited parental appreciation of the amount of violence in a game: 64% of "everyone-rated" video games and 94% of "teen-rated" games contain violent acts; mature-rated games often contain more and different violent content than what is described on the label.[35-37] Eighth and ninth graders who play video games frequently get into more arguments with teachers, get into more physical fights, and see the world as a more aggressive place.[38] Further, research shows that school shootings often relate to violent video games in which the player experiences killing others through the eyes of a protagonist.[39] Whereas computer use and video game use were the strongest factors related to violent behavior,[40] a causative link has not been established.[41]

ADOLESCENTS, DRUG ABUSE, AND VIOLENCE

Alcohol and drug use among youth is common. Among high school students in 2009, 73% had tried alcohol, 24% had had five or more drinks at one time, 37% had used marijuana, 3% had used cocaine, 4% had used methamphetamine, and 12% had used inhalants.[42] In youth 12 to 17 years of age, 4.6% are dependent on alcohol and 7.0% are dependent on illicit drugs, and 1.8 million children require alcohol or drug treatment each year.[43]

From the ages of 10 to 13 years, children begin experimenting with a wide range of new behaviors. Cigarettes, alcohol, and other types of drugs are a normal part of the "coming of age" for many children, regardless of race, culture, socioeconomic status, or geographic location. Substance use follows a predictable pattern, beginning with experimentation with cigarettes and alcohol, followed by marijuana, then cocaine. Other drugs, including opioids and hallucinogens, typically are tried later, but an adolescent does not necessarily progress beyond a particular stage. Initially, the adolescent associates drugs with euphoria and pleasure. With regular use, tolerance and the need for particular drugs develop. At this stage, the adolescent is drug dependent and now uses the drug to prevent withdrawal symptoms, which may be physiologic or psychological in nature. For adolescents, any use of a drug constitutes drug abuse. Adolescents at greatest risk for lifelong substance abuse typically begin to use drugs before the age of 15 years. Adolescents who are the most affected by substance abuse are those who are least involved in school or other meaningful activities.

The precise relationship has not been completely elucidated, but drugs and violent behavior are related to drug use (pharmacologic violence), to drug procurement (economic violence), and to the illicit sale of drugs.[44,45] Alcohol is the most common drug associated with violence. The pharmacologic effects of alcohol contribute significantly to the prevalence of adolescent fighting, suicide, homicide, unintentional injury and death, rape, and physical assaults.[46] Cocaine, barbiturates, phencyclidine (PCP), amphetamines, and anabolic steroids as well as increasingly available medications used for attention deficit disorder and hyperactivity also play a role in such violence.[43] Youth who had used an illicit drug in the past year are almost twice as likely to have engaged in a violent act as those who do not use an illicit drug, and the likelihood of engaging in violent behavior increased with the number of drugs the youth had used in the past year.[47] Economic violence during the process of obtaining money to finance drug use can lead to intentional and unintentional injury and death. Violence between buyers and sellers includes robbery for money or drugs, arguments over drug quality or quantity, competition for territory or markets for the sale of drugs, and violence as a management strategy to discipline drug-selling subordinates.

FIREARMS AND YOUTH

Death caused by firearms occurs 90 times more frequently in the United States than in any other industrialized nation.[8] In the United States, four children and adolescents are killed by firearms every day.[48] For every child killed, three children sustain a firearm-related injury.[49] Sixty percent of firearm assaults are fatal, compared with 4% of knife assaults and less than 1% of assaults with blunt objects.[50] Exposure to firearm violence doubles the probability that a youth will commit violence within 2 years.[51]

There are approximately 218 million privately owned firearms, of which 85 million are handguns.[52] Handguns are involved in most firearm injuries and deaths, although they make up less than one third of all firearms. About half of all households in the United States contain a firearm. Most privately owned firearms are purchased with the intent of increasing personal safety and home security, but the risk of firearms in the home is unrecognized.[53] A firearm in the home is 43 times more likely to kill a family member or friend than an intruder.[54] A handgun is the weapon used in 82% of adolescent homicides.[55] When a gun is fired in the home by an adolescent, the victim most often is the adolescent (35%), a friend (34%), a sibling (25%), or a parent or relative (6%).[2] Many firearms in the home are stored unlocked and loaded.[56] In one survey, three fourths of children younger than 14 years knew exactly where the firearm in their house was located, and one third had handled it.[57] Before 8 years of age, few children can distinguish between a toy gun and a real gun.[53]

The availability of firearms increases the lethality of violent behavior,[58] and easy accessibility plays a major role in the morbidity and mortality of children and adolescents. In recent decades, there has been a 75% increase in child and adolescent firearm deaths.[50] The firearm death rate among U.S. children aged 14 years and younger is approximately 12 times greater than the firearm death rate among children in 25 other industrialized nations combined,[59] and again, firearm availability has been correlated with this increased rate.[60] Firearm homicide rates are highest among African American adolescent boys in urban areas in the United States,[61] for whom firearm injury is the leading cause of death. Among adolescents, firearm homicide occurs most often in urban areas, and suicides occur most often outside urban areas. Children in the most deprived socioeconomic quintile had a 159% higher firearm homicide rate compared with those in the least deprived quintile.[62]

www.ketabpezeshki.com 66485457-66963820

NON-POWDER FIREARMS

Modern technology has transformed the BB gun from a toy to a potentially lethal weapon with a muzzle velocity in the range of small-caliber, low-velocity powder firearms. Other non-powder firearms include pellet guns and air pistols that use spring-loaded, manual pump compression or pressurized carbon dioxide instead of gunpowder and can cause severe injury or death at close range.[62]

Non-powder firearms are used predominantly by children and adolescents, and 80% of all injuries by non-powder firearms are in these age groups.[63] These injuries account for 23,000 emergency department (ED) visits per year.[64] Victims of non-powder firearm injuries are overwhelmingly male. Injuries to the extremities are the most common, but 33% of injuries involve the eyes, head, face, or neck.[65] In one study of pediatric patients presenting to a trauma center with non-powder firearm injuries, 57% sustained serious injuries, with 30% requiring operative treatment and 7% dying.[66] The most significant injuries are intracranial penetration in the region of the orbit or thin regions of the skull. Non-powder firearm injuries are a common cause of blindness in adolescent boys; other less well known complications include remobilization and lead poisoning. Penetration of the heart and aorta occasionally results in death. Overall, non-powder firearm injuries are more numerous and less severe than powder firearm injuries, but head, chest, and abdominal wounds from these weapons may be erroneously regarded as trivial, with catastrophic results.[62]

PREVENTION STRATEGIES FOR YOUTH VIOLENCE

Children and adolescents lack judgment and experience and cannot be expected to avoid violence and injury on their own.[67] Risk factors for youth violence include history of violence victimization, exposure to violence, access to weapons, substance abuse, antisocial beliefs, low parental involvement, low income, poor academic performance, social rejection, low levels of community participation, and high levels of community transience. Factors associated with less violent behavior include high grade point average, strong religious beliefs, connectedness to family, ability to discuss problems with parents, and large amounts of social capital in the community.[68] Physicians should screen for these risk factors to identify youth at risk for violence.[69-71]

Many medical associations, including the American College of Emergency Physicians, have policy statements calling for physicians to incorporate youth violence prevention into their practices. To decrease youth violence, physicians and other health care providers should urge the media to do the following: decrease the violence, use of weapons, and pain and suffering depicted in the media; accurately portray the true consequences of violent acts; and decrease the amount of violent lyrics and violent scenes in music videos and video games. Physicians should advise parents to monitor and to limit their children's viewing of television, video games, music videos, movies, and the Internet.[69]

Health care providers can also work directly with schools to address youth violence.[8,72,73] Schools should be encouraged to teach conflict resolution and anger management skills, which represent an empowering step toward avoiding violence. Further, schools can make the learning environment physically safer by decreasing the number of weapons carried by students. Students should be advised of the risk and legal consequences of bringing weapons to school. Depending on the school and local community, metal detectors and school safety police may be necessary. Schools and health care providers should work jointly with local communities to decrease violence that occurs on the way to and from school and the overall level of violence in the community.

Emergency physicians and other health care providers should encourage school-based counseling concerning violence and injury prevention.[74] This may be a cost-effective method of preventing childhood and adolescent violence.[75,76] Physicians should educate children, adolescents, and their parents about drug use leading to abuse and dependency and the association between drugs and violence. Physicians should also educate parents about the risk of firearms kept in the home and, if a firearm is present, the proper storage (i.e., unloaded, separated from ammunition, and in a locked box or cabinet). Parents should ask about firearms when their children visit other homes and allow their children to use non-powder firearms only with goggles, chest protection, and adult supervision.

Rates of youth violence-related recidivism and retaliation are extremely high,[77,78] and the ED is often the first point of contact between the health care provider and both victims and perpetrators of violence; for a large number of patients, the ED is the only location in which they receive health care.[79,80] Screening tools focusing on questions such as whether the patient has recently been in a fight, been injured by violence, or been threatened can identify at-risk youth.[76] ED-based intervention programs that immediately identify at-risk youth and link them to educational, community, and health care resources as well as social work follow-up have decreased violence, delinquency, drug use, and victimization.[81] Brief counseling by the treating physician may also be an effective first step.[79]

Acutely, the emergency physician should determine whether a victim of violence plans to seek revenge and provide immediate counseling emphasizing a cooling-off period to prevent further acts of violence. The risk of reinjury or death to the patient and others and the risk of criminal prosecution should be discussed. Health care providers should check with local laws to determine whether they may be legally bound to report to law enforcement officers if the patient threatens a specific individual.[82,83]

VIOLENCE BY STREET GANGS

Street gangs are mainly composed of inner-city adolescents from the same socioeconomic background. Adolescents join street gangs for a sense of belonging, protection, status, adventure, and illegal monetary gain, but most inner-city youth do not join street gangs.

In the 1950s, when street gang violence typically involved fist-fights, blunt objects, knives, and only rarely firearms, there was a much lower chance of serious injury or death to gang members or innocent bystanders. Modern-day street gangs are larger, more numerous, more widespread, more violent, and no longer confined to the inner city. Since firearms have become the weapons of choice, more gang members and innocent bystanders are injured or killed,[84] and gang density is directly correlated with higher community homicide rates.[85] Drug use and selling, violence, and vandalism significantly increase the likelihood of joining a gang.[86] Gang members, as the ultimate defenders of intrusions in their neighborhood or on their turf by rivals, are often willing to die, to risk imprisonment, to kill rivals, or unintentionally to injure or to kill innocent bystanders. If a rival street gang insults, challenges, injures, or kills a member of another street gang, it is highly probable that another episode of violence (i.e., retribution) will occur. Being injured, imprisoned, or killed defending the gang or turf often enhances a gang member's reputation and standing in the gang. The more violent the street gang, the greater the reputation of the gang members. Gang members commonly do not testify in court against rival gang members but prefer to enforce their own brand of retributive justice, violently, against rival street gangs. Common reasons for street gang violence include retaliation for previous shootings, rivalry, turf fights, arguments, and, at times, control over an illegal criminal

www.ketabpezeshki.com 66485457-66963820

enterprise. Injuries and homicides by violent street gangs occur in many ways, including walk-up shootings, drive-by shootings, stabbings, use of blunt force weapons, and arson. In most instances, intentional street gang violence is intraracial.

Violent street gangs are active in 99% of U.S. cities with a population of more than 100,000[87] and in 32.4% of all cities. In 2008, it was estimated that there were 27,900 gangs with approximately 774,000 gang members nationwide.[88] Modern street gangs nationwide have patterned themselves after the 1980s street gang subculture in the Los Angeles area. The street gang subculture has its own style of dress, form of verbal and nonverbal communication, music, camaraderie, and funeral rituals, which has made it possible for adolescents of any ethnic group or background to identify with the gang lifestyle.[89,90] Gangs are frequently based on ethnic or racial association. Some white gangs differ from other groups in that they are consistently involved in acts of hate violence.[91] Life in the gang typically begins around the age of 13 years as a "wannabe," with most adolescents joining the gang at around 15 years. The peak ages for violent street gang activity are between 15 and 21 years,[92] after which gang members begin to migrate out. Some members stay active in the gang into their early 30s.[93] There is growing concern that gang violence is spreading to and through the Internet, consistent with the increasing use of this media by adolescents and youth.[94] The most likely reasons for increasing gang violence include the growth in the number of gang members, the appeal of the bravado and violent image of gang members, the greater levels of intergang violence, an increase in the sophistication of firearm weaponry in gang violence, an increasingly violent society, an increased economic despair in urban communities, a breakdown in sociocultural institutions, and an increase in marginalization of urban children and adolescents.[95-97] A causal relationship of increasing drug use with gang violence and homicide has also been shown.[98,99]

Drive-By Shootings

One of the most dangerous violent acts committed by street gangs is the drive-by shooting, defined as gang members shooting at suspected rival gang members from a vehicle. Violent street gangs perpetrate more than 90% of all drive-by shootings. The primary purpose of a drive-by shooting is to create fear, terror, and intimidation among members of rival street gangs. The secondary intent is to kill.[93] Drive-by shootings mainly occur at night in the inner city and generally last 5 to 15 seconds.[100] Drive-by shootings are not random events.[101] Most frequently, drive-by shootings occur on public streets, with gang members shooting into cars of suspected rival gang members but also shooting into the homes of suspected rival gang members, in parks, and around public schools.[101] In many drive-by shootings, gang members flash their gang hand sign (a form of nonverbal gang communication) and yell their gang name. This makes it known to all rival gang members which gang was actually shooting at them. Most drive-by shooters are not apprehended by law enforcement.

No longer confined to the inner city, drive-by shootings are now a national phenomenon and endemic in some regions of the United States.[102] Drive-by shootings are a major public health problem because many individuals can be injured or killed in one incident.[103] In one study, 63% of children and adolescents who were targeted sustained a firearm injury, and 5.3% died of their injuries. Thirteen people are injured for each individual killed in a drive-by shooting.[101] For adolescents and young adults, the lower extremity is the most frequently injured body region, followed by the upper extremity. The most frequent fatal injuries are to the chest and head.[101] Most small children injured or killed in drive-by shootings are unintentionally caught in the crossfire of gang shootings.[104] These small children frequently sustain fatal firearm injuries to the head, neck, and chest.

Firearms and Violent Street Gangs

The weapon of choice in a drive-by shooting is a 9-mm semiautomatic handgun. Some semiautomatic handguns may fire 15 or more bullets before reloading. The high-capacity, rapid-fire mechanism of a semiautomatic firearm helps explain why many individuals may be injured or killed in a single drive-by shooting.[100]

For many gang members, firearms fulfill the need for power, status, protection, and progression from adolescence into adulthood that is no longer being met by traditional sociocultural institutions. Firearms are used in 95% of gang homicides[84] compared with 69% of all homicides.[48] Handguns—particularly semiautomatic handguns—are the most commonly used weapon in gang shootings, followed by shotguns, rifles, and assault weapons used in 8%, 5%, and 3% of all gang homicides, respectively.[84]

Psychological Effects of Street Gang Violence on Children and Adolescents

Some urban communities have higher exposure to street gang violence than others do.[8,105] In one group of inner-city adolescents, nearly 85% had witnessed at least one violent act, and 43.4% had witnessed a murder.[106] Children and adolescents living in the inner city are exposed to chronic, pervasive violence rather than isolated episodes of violence. The reactions of these children to this pervasive violence are consistent with those of children and adolescents living in war zones.[107,108]

On exposure to repetitive or extreme acts of violence, children and adolescents may show signs of sleep disturbance, difficulty concentrating in school, flashbacks, hypervigilance, increased risk-taking behavior, and a nihilistic, fatalistic orientation to the future.[109] Many of these children may also suffer from post-traumatic stress disorder. The severity of a child's or adolescent's reaction to a gang shooting is related to proximity to the shooting, threat to the child's or adolescent's own life, his or her relationship to those who were injured or killed in the shooting, and whether gang violence is endemic in the community.[109]

Children and adolescents living in communities where there are many street gangs often receive little or no counseling for the physical and psychological sequelae resulting from gang violence. The net psychological effect of exposure to gang violence on children and adolescents is unknown, but it potentially desensitizes children and adolescents to violence and leads to carrying of a weapon out of fear for their own personal safety.

Preventing Gang Violence in the Emergency Department

With the increase in gang violence nationwide, emergency physicians and other health care providers have become vulnerable to injury and death from gang incidents in the hospital. The development of guidelines for the prevention of gang violence is recommended to safeguard emergency physicians, other health care providers, patients, and visitors.[110]

In the past, recognition of local street gangs was determined by tattoos, "colors" (e.g., blue for Crips, red for Bloods), typical clothing (e.g., baggy pants, athletic team jackets), specific accessories (e.g., sneakers, caps, belt buckles, bandannas), and hand signs; many of these styles, however, have now become popular in all segments of society. Information about local gangs may be obtained from community activists involved in gang prevention programs or local law enforcement agencies. All health care providers should know the root causes of violent street gang formation, the effects of gang violence on the community, and the prevention of street gang violence.

www.ketabpezeshki.com 66485457-66963820

Emergency Department Guidelines

- On the arrival of injured known or suspected gang members, hospital security should be immediately involved, should be stationed in the ED and waiting area, and should secure the hospital perimeters.
- Consistent with the primary survey examination, the patient should be undressed and searched for concealed weapons with the assistance of security or law enforcement.
- The evidence of previous major trauma (e.g., laparotomy, thoracotomy, thoracostomy scars) or tattoos may be indicative of previous gang injuries.[111]
- In a calm, nonjudgmental fashion, emergency health care providers should ask the patient whether he or she is a gang member.
- ED staff should not challenge or insult known or suspected gang members. In the street gang subculture, perceived disrespect often leads to a violent confrontation.
- While the patient is in the ED, visitation should be limited, preferably to the patient's parents. Other visitors (e.g., friends and relatives) can be kept informed by periodic updates from the ED staff.
- If admission is required, gang members should be admitted under "John Doe" or Jane Doe" status to protect their identity and to avoid an outbreak of gang violence in the hospital.
- Hospital security should be available 24 hours a day and should maintain high visibility and vigilance when injured gang members are present in the ED.
- If gang members (in particular, rival gang members) are found to be present in the ED or waiting area, hospital security should be present and local law enforcement should be advised.
- Although concerned for their personal safety, ED personnel should not arm themselves with firearms or other weapons while on duty. Health care providers with weapons potentially could escalate the level of violence in the ED. Gang members might view health care providers as adversaries.
- Community leaders who are experienced with local street gangs may act as mediators between the ED staff and members of violent street gangs. These mediators should be summoned to help decompress any hostile situations that may arise.
- Hospitals should have lock-down or evacuation plans for ED personnel and visitors in the event that violence erupts within the ED.
- The ED staff should learn to recognize and to de-escalate previolent aggressive behavior.
- The ED should keep a log of all violent incidents that occur within the ED. This strategy helps quantify the severity of and weapon use in violent incidents and helps determine the necessity for other security measures (e.g., video cameras, metal detectors, bulletproof glass, armed safety police).

As long as gang violence exists in the community, spillover of the violence into the ED is likely. With appropriate concern for their own safety, ED personnel should deliver compassionate care to all members of violent street gangs while minimizing their own risk of injury.

Prevention of Street Gang Violence

Law enforcement and the criminal justice system alone cannot solve the violence of street gangs. The United States should develop a national policy on the issue of violent street gangs, with an emphasis on alleviation of the root causes of violent street gang formation. The root causes of violent street gang formation include poverty, stressed families, lack of education, unemployment, underemployment, racism, marginalization, and breakdown of sociocultural institutions. Although incarceration is a part of the solution, primary prevention through alleviation of the root causes of violent street gang formation would be more effective. For truces among violent street gangs to be effective, they should be supported by concerted efforts to alleviate the root causes of violent street gang formation.[84]

Some gang members are receptive to leaving the gang after being injured or after a fellow gang member has been injured or killed in violent street gang activity.[112] Accordingly, attempts to break the cycle of gang membership should occur when injured gang members present to the ED. Hospital-based interventions should begin in the ED and continue throughout the hospitalization. On discharge from the hospital, counseling should continue to intervene further in breaking the cycle of violent street gang involvement. Because many individuals in the community, particularly children and adolescents, may experience the physical and psychological effects of violence, counseling should be made readily available.

Any prevention strategy with a unilateral focus would be unsuccessful in decreasing violent street gang activity and breaking the bonds of gang membership. The solution to street gang violence should use a multifaceted approach.

KEY CONCEPTS

- Youths are particularly vulnerable to and disproportionately affected by violence.
- Physical, verbal, and relational violence in schools is common.
- Media violence, drugs and alcohol, and access to firearms have been associated with increased youth violence.
- Street gangs continue to be a major source of youth violence.
- Involvement of health care providers in youth violence prevention is effective and should occur in the ED.

Medical Literature and Evidence-Based Medicine

Kelly D. Young and Roger J. Lewis

PERSPECTIVE

Medicine is an empirical science based on the experiences and insights of past and contemporary practitioners. Because the clinical experience of an individual physician is a small fraction of the experience of the medical profession as a whole, the advancement of medical science depends on physicians' abilities to assemble, to organize, and to disseminate information to learn from the experience of others.

The Medical Literature

During the past several decades, medical literature has exploded.[1,2] Thirty years ago, physicians could understand most medical publications. Currently, reports frequently use sophisticated statistical analyses that are unfamiliar to most clinicians.[3] Emergency physicians and other practitioners are increasingly aware that the quality of the research reported should be evaluated before the results can be considered valid and clinical practice altered. Also, the results of quality research may not be applicable if the population studied differs greatly from the population of patients in the emergency physician's clinical practice. Even a clinician who possesses the analytical skills necessary to understand and to interpret the modern medical literature will find it difficult to remain current, given the rate at which medical studies relevant to emergency medicine are published. Thus the emergency physician should have a plan to identify, to select, and to read high-quality, relevant articles. Furthermore, the emergency physician should understand a number of principles to be able to analyze published studies critically.

The first step toward achievement of these goals is to identify a small number of journals on which to focus.[4,5] Most high-quality studies relevant to emergency medicine are published in fewer than a dozen journals. Once a list of 6 to 12 journals is compiled, back issues can be skimmed to determine the average number of relevant articles in each issue. Those journals that publish the highest number of articles directly relevant to an emergency physician's clinical practice should then be selected.[4] An emergency physician in full-time clinical practice should probably focus on two to six journals per month. Regular pamphlet, audio, or Internet-based updates reviewing recent literature relevant to emergency medicine can be purchased and used as a supplement or to guide journal review. Articles should be pulled and read in full, however, before results are accepted and clinical practice is altered.

Possible articles should then be screened to evaluate the relevance of the study question and population and to determine whether the methodology is of sufficient quality to warrant reading of the article in more detail. Quality and clinical relevance vary greatly in the peer-reviewed literature.[4] Only articles that meet high standards for methodological quality should be read in detail.[1,2] The emergency physician should learn to differentiate high-quality studies from poor-quality studies with unreliable results. Practitioners who understand the concepts presented in this chapter will have the basic foundation to differentiate good from poor studies and to focus their reading on those studies most likely to yield results that warrant a change in clinical practice. Additional guidance can be obtained from the *Journal of the American Medical Association's Users' Guides to the Medical Literature* series (www.jamaevidence.com).[6]

A steadily increasing amount of attention is being paid to the importance of rigorous methodology in the design and execution of clinical trials.[3,7-9] A poorly designed statistical analysis can yield misleading results, but a trial is more likely to be weakened by a poorly chosen question, an inappropriate study population, or other methodological errors that bias the results.[10-17] Thus, although some degree of statistical literacy is important, the practitioner should also understand nonstatistical issues in the design and conduct of clinical studies.[6,10-17]

TYPES OF CLINICAL STUDIES

Studies can be divided into two categories, cross-sectional and longitudinal (cohort), by when the measurements are made on the study population.[12] In a cross-sectional study, data are obtained from a population of patients at a single point in time, whereas in a longitudinal study, data are obtained from a population of patients during a period of time.

Cross-Sectional Studies

Many epidemiologic studies are cross-sectional. Although a cross-sectional study cannot prove a causal relationship between a risk factor or treatment and an outcome, strong associations between identified variables in cross-sectional studies are suggestive of such effects.[18]

Many important observations can be made only by use of cross-sectional studies because, for practical and ethical reasons, some variables cannot be artificially manipulated to determine their effect on patient outcome.[18] Furthermore, the effect may be so delayed that a longitudinal study is impractical. An example is a study examining the association between cigarette use and lung cancer. It would be unethical to expose a nonsmoking population to the effects of cigarettes, and even if one were to identify a population that would voluntarily use cigarettes, it would be impractical to observe subjects long enough for malignant neoplasms from cigarette smoking to appear. However, a cross-sectional study of self-reported cigarette use and the diagnosis of lung cancer that

www.ketabpezeshki.com 66485457-66963820

examines a population of subjects at a single point in time can easily demonstrate an association.

Longitudinal Studies

In a longitudinal, or cohort, study, a population of patients is enrolled in the study and measurements are made during a period of time.[11,12] Longitudinal studies can be observational, if no intervention is made, or they can be interventional.

Longitudinal Observational Studies

In a longitudinal observational study, data are collected from a group, or *cohort,* of patients over time, but no intervention is made. A longitudinal observational study can be either prospective or retrospective. In a *prospective* observational study, patients who meet specific eligibility criteria are identified, and data are prospectively gathered over time.[12] Prospective observational studies are valuable for defining the course of a particular disease treated with standard therapies and for identifying subgroups of patients with differing prognoses. If an association is noted between treatment and outcome in a prospective observational study, the association should be verified in a prospective interventional randomized clinical trial.

Although an observational study cannot prove a causal relationship, associations between initial patient characteristics or specific treatments and subsequent outcome can be detected. Such associations can be measured more accurately in a prospective longitudinal study than in a cross-sectional study because both the original patient characteristics and the subsequent outcome are determined prospectively. When these are determined prospectively, any associations observed are more likely to be true and not a result of measurement error or recall bias.

In a *retrospective* observational study, medical records of patients with certain initial characteristics who are treated over time are reviewed and data abstracted. As with all retrospective studies, retrospective observational studies are subject to recording bias, problems with missing information, and other methodological limitations. Because retrospective studies have these additional limitations and sources of bias, prospective studies provide higher quality evidence than retrospective studies do. Prospective studies, however, are usually more difficult and time-consuming to perform.

Longitudinal Interventional Studies (Clinical Trials)

Interventional studies, which must be prospective, involve the artificial manipulation of a patient's therapy to determine the effect of an investigational treatment.[11,12] An interventional study can be controlled or uncontrolled, and if it is controlled, the treatment assignment should be randomized.

In an *uncontrolled* interventional study, all patients who meet defined eligibility requirements are given the investigational therapy, and their outcomes are determined. Although such studies are useful to define the rate of successful therapy in a well-defined population of subjects, the lack of a control group makes it difficult to estimate the relative effectiveness of the new therapy compared with another therapy. Previous experience with the standard treatment, in the form of a historical control group, can be used for comparison to the group receiving the new therapy. The use of such historical control groups is unreliable and often leads to an overestimate of the relative effectiveness of the new investigational therapy.[16] Medical care is generally becoming more effective, and thus the results of modern studies tend to yield better patient outcomes, even if the investigational treatment has no inherent advantage over the therapy received by the historical control patients.[16]

In a *controlled* clinical trial, some patients are given the new investigational treatment, and some patients (*control group*) are given a standard treatment.[11,12] The purpose of the control group is to define the effectiveness of the standard therapy in a group of patients as similar as possible to the group receiving the investigational therapy. To obtain two groups of patients who are nearly identical with respect to all characteristics that might influence the outcome of their disease, it is important that no external or subjective factors influence the assignment of treatment.[11,17] In other words, each patient must have the same chance of receiving each therapy. For this reason, assignment to control or therapy groups should be randomized.

It is extremely important that control patients be given a therapy that is at least as effective as the best currently available treatment. It is unethical for a control group to receive an inferior treatment simply to demonstrate that a new treatment has some effectiveness.[19-22]

In general, longitudinal interventional studies provide the highest quality evidence, although this is controversial.[23-25]

RANDOMIZED LONGITUDINAL INTERVENTIONAL STUDY (CLINICAL TRIAL)

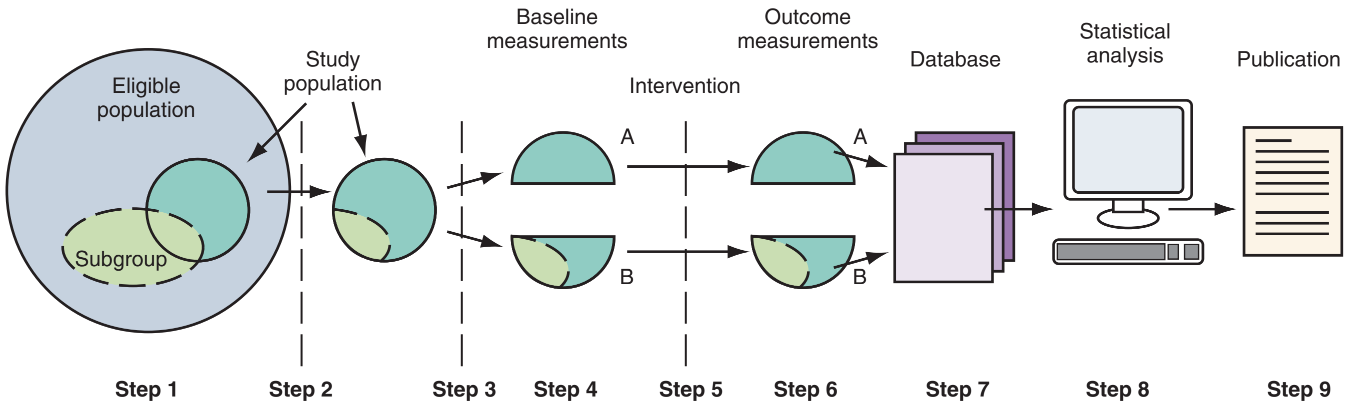
A randomized clinical trial should not be initiated unless a worthwhile research question has been precisely defined (Fig. 1). No matter how well designed the study, if the research question is not well defined and not clinically useful, the intended audience will not find the study's results valuable.[26] The research question must also be prospectively defined; it is not appropriate to gather data and then to devise a research question to fit the data. A good research question clearly defines four elements: (1) the patient population and problem to be studied, (2) the intervention to be applied to the treatment group, (3) the comparison (control) intervention, and (4) the outcome of interest.

Even if these four elements are well defined, the research question must still have relevance for the emergency physician. For example, a study that compares oral and parenteral antibiotics (treatment and comparison interventions) for the prevention of meningitis (outcome) in well-appearing febrile children with occult bacteremia confirmed by positive blood culture (patient population) is less useful to the emergency physician than a similar study including all well-appearing febrile children because results of blood cultures are not typically available in the emergency department.

Step 1: Definition of Patient Population

Assuming an appropriate research question has been selected, the first step is to define the patient population to be studied.[27,28] The original patient population defined in the research question may be modified slightly by practical factors in study design. For example, although an investigator may want to study all asthmatic patients presenting to the emergency department, it may be practical to study only those presenting when investigators are available (*convenience sample*). Explicit inclusion and exclusion criteria must be defined before any patients are enrolled, and these criteria must be uniformly applied in determining which patients are eligible to participate in the study. For the study to be most applicable to emergency medicine, the population should be defined in terms of clinical characteristics that are observable in the emergency department. On the other hand, groups of patients defined by their clinical characteristics in the emergency department are highly heterogeneous.[13] Some patients in the population may have more severe disease than other patients or may have a completely different cause of their symptoms.

www.ketabpezeshki.com 66485457-66963820



Step 1: Definition of the patient population	**Step 2:** Recruitment and enrollment of patients	**Step 3:** Randomization	**Step 4:** Measurement of baseline characteristics	**Step 5:** Treatment or intervention	**Step 6:** Collection of data on outcome	**Step 7:** Data management	**Step 8:** Statistical analysis	**Step 9:** Presentation and publication of results
Problem 1: Heterogeneous population (confounding variables), poorly chosen inclusion criteria	**Problem 2:** Bias in recruitment, self-selection by potential subjects	**Problem 3:** Imbalance of important confounding characteristics, inadequate blinding	**Problem 4:** Imbalance of confounding characteristics is not detected	**Problem 5:** Unequal compliance or attrition	**Problem 6:** Subjects lost to follow-up, poorly defined outcomes	**Problem 7:** Data entry errors, data reduction errors or bias	**Problem 8:** Type I and type II errors, ill-advised comparisons or subgroup analysis, covariate imbalance	**Problem 9:** Overextrap-olation of results, failure to recognize limitations of or biases in results
Solution 1: Population defined in terms of emergency department presentation, confounding characteristics considered in definition of population	**Solution 2:** Consecutive enrollment, records of nonenrolled but eligible patients	**Solution 3:** Effective randomization and blinding, stratified randomization	**Solution 4:** Planned prospective measurement of important confounding characteristics	**Solution 5:** Intention-to-treat analysis of final data, measurement of compliance, procedures to encourage compliance	**Solution 6:** Multistep plans to obtain follow-up data, unambiguous definitions of treatment outcome	**Solution 7:** Data verification, double data entry, value-limited data entry, appropriate forms design	**Solution 8:** Small number of comparisons, planning of analysis, adequate sample size, multivariate modeling	**Solution 9:** Peer review, replication of results by other investigators, educated readership

Figure 1. Implementation and analysis of a prospective randomized, controlled clinical trial.

When reading a study, one should determine if the patient population is well defined and reasonably comparable to one's own patient population.[6] If important segments of the population are excluded (e.g., those with severe disease), the study results are not applicable to this subgroup. Researchers should not generalize their conclusions to patients not included in their study population.

Step 2: Recruitment and Enrollment of Patients

Once a patient population is defined, the next step is to recruit patients for enrollment in the study. To the extent possible, all patients meeting the predefined eligibility requirements for the study should be enrolled. The method of recruitment and enrollment should ensure that there is no systematic tendency to exclude a subgroup of patients from the study who meet the inclusion criteria. If such a *selection bias* exists, it will make the results of the study inapplicable to the types of patients that were excluded.[11,29] For example, if a study of head trauma patients specifies that informed consent must be obtained from the patient within the first half-hour of presentation to the emergency department, there will be a systematic tendency to exclude patients with head trauma severe enough to result in an altered level of consciousness.

Even in a study that is appropriately designed, patients may self-select, resulting in selection bias. For example, patients of low socioeconomic status may be either more or less likely than patients of high socioeconomic status to give consent for participation in clinical studies. Thus, although the disease may affect people in all socioeconomic strata, the study results may apply only to patients of socioeconomic status similar to those who participated in the study.

To minimize selection bias, studies should aim to achieve consecutive enrollment of all patients who meet inclusion criteria. Furthermore, patients who meet eligibility criteria but are not subsequently enrolled should be counted to allow an estimation of the possible extent of any selection bias that might exist.[10] When reading a study, one should look for information on eligible patients who were not enrolled. A significant number of such patients may indicate selection bias. Researchers should explain why these patients were missed and should justify the validity of their results despite missed patients by showing, for example, that demographics and disease characteristics of missed patients were similar to those of enrolled patients.

Step 3: Randomization

The third step in conducting a clinical trial is to randomize enrolled patients to the different treatments being compared. The purpose of this randomized allocation is to create two groups of patients who, other than receiving different treatments, are as nearly identical as possible.[11]

Stratified randomization can be used to ensure that important confounding factors are equally distributed in the control and test groups.[11] In a stratified randomization, patients with the stratifying characteristic are randomized independently of those without the characteristic. For example, in a study of therapy for closed head injury, patients with severe closed head injury as defined by a low Glasgow Coma Scale score could be randomized independently of those patients with a higher Glasgow Coma Scale

www.ketabpezeshki.com 66485457-66963820

score. This would help ensure that the control and test groups have equal fractions of patients with severe and mild closed head injury.

Whenever possible, both the patient and the treating physician should be "blinded" (*double blinding*) to the therapy given.[11] Such blinding is important to ensure that both the patient and the investigating physician can make unbiased estimates of endpoints, including the occurrence of undesirable side effects. Recently, increasing importance has been placed on subjective outcomes, such as quality-of-life assessments made by the patient. Blinding is especially important to ensure that the patients' expectations regarding the effect of the new therapy do not influence their assessment of this type of outcome.

The quality of the randomization in a controlled clinical trial is important because studies that are inadequately randomized are more likely to "find" a positive treatment effect even when one is unlikely to exist.[30] Similarly, studies in which blinding is inadequate, so that the patient or the treating physician might be able to determine the treatment that the patient actually receives, are more likely to yield false-positive results.[15] When reviewing a clinical trial, one should look for truly random treatment assignment and adequate blinding procedures. For example, in a trial in which patients are enrolled only if they are determined to be sufficiently "stable" by the physician and assignment to therapy or control is alternated, a physician with the bias that the therapy is not efficacious may avoid enrolling a patient by deeming the patient unstable if the physician knows that the next patient will be assigned to the treatment group. A better method of randomization would be assignment by a computerized randomization program, such that no pattern of assignment can be discerned by the enrolling personnel.

Step 4: Measurement of Baseline Characteristics

The fourth step is to measure the characteristics of patients enrolled in the study before therapy. The purpose of these baseline measurements is to detect imbalance between the control and test groups in characteristics that might influence each patient's chance for a successful outcome. Factors that might influence patient outcome and that are not controlled by the investigators are termed *confounding variables.* For example, the initial cardiac rhythm is a confounding variable in a study that compares different treatments for out-of-hospital cardiac arrest. If one group includes more patients in ventricular fibrillation and the other group has more patients in asystole, the intervention given to the first group will appear to be more efficacious. The influence of confounding characteristics must be anticipated, and those characteristics should be prospectively measured for all patients enrolled in the study. Subgroups of the overall patient population often have specific confounding characteristics (see Fig. 1). If a clinically significant difference in outcome is ultimately detected between the two treatment groups, the baseline characteristics of the treatment groups should be compared to ensure that the observed difference in outcome did not occur because the two patient groups were not initially equivalent.[11] When reading a study, one should look to see that important confounders were measured and that they did not differ substantially between the groups studied.

Step 5: Treatment or Intervention

The next step is to administer the experimental treatment to the test group and the control treatment to the control group. Although the control and test patients should be nearly identical in their underlying characteristics, the two groups often have unequal compliance with therapy. For example, in a placebo-controlled study of an oral medication, patients taking the active drug may find that it causes gastrointestinal discomfort, whereas those taking the placebo treatment might not experience such an effect. Therefore, patients taking the active agent may be less compliant with therapy. Unequal compliance complicates the interpretation of the outcome data.

Step 6: Collection of Data on Outcome

The sixth step is to determine the outcome of each patient. Definitions of treatment success and treatment failure must be explicitly defined before any data are collected. Sometimes a trial is initially designed to investigate the effects of therapy on one outcome, but during data analysis investigators notice an apparently significant effect on a different outcome. Such a serendipitous finding may reflect a true treatment effect but can also result from chance because there are generally many such possible findings, and the study was not originally designed to investigate each of these possible outcomes. Such findings can be reported as interesting and warranting further investigation but should not be reported as reliable conclusions.

A difficulty with the collection of outcome data arises if too many subjects are lost to follow-up. This is more likely to occur in studies that evaluate the long-term effects of therapy. Patients who are lost to follow-up may have characteristics different from those of patients who keep their follow-up appointments. For this reason, lack of complete follow-up in the study population can bias the results of the study.

Ensuring high rates of follow-up in studies of outpatient therapy is notoriously difficult. One approach is to create a multistep plan to obtain follow-up, with specific procedures to be followed if patients miss their first, second, or even third follow-up appointment. When reading a study, one should look at the percentage of patients lost to follow-up and look for a systematic effort to maintain good follow-up.

Step 7: Data Management

Once patients have been enrolled and have had their baseline characteristics measured, treatments administered, and outcomes determined, all this information should be organized and stored in a format that allows analysis of the data. Data should be collected on a form that limits and organizes the information. In general, information to be recorded on the data form should be highly structured, with categorical variables limited to a small number of possibilities and with very little or no unformatted "fill-in-the-blank" information requested. Such structure is required if the resulting data are to be analyzed statistically.

Errors may be introduced when data are entered into the database from data sheets. Bias can be introduced if certain types of data (e.g., written phrases in a patient questionnaire) are reduced to a smaller number of categorical responses during the data entry procedure. Databases should be designed to ensure that the data listed are reasonable. For example, the electronic database should not allow entry of patient temperatures that are incompatible with life or negative blood pressures. When reviewing a study, one should look for data categorizations that are clear and clinically useful. For example, a study of postresuscitation neurologic outcomes would be most useful to the emergency physician if patients were categorized as "normal," "mildly impaired," "severely impaired," or "dead" versus the more vague terms "good" and "poor" or by the results of a detailed neuropsychological battery of tests.

Step 8: Statistical Analysis

The next step is to analyze the data. Careful planning of the statistical analysis to be performed is required to minimize the chance

www.ketabpezeshki.com 66485457-66963820

of erroneous conclusions. Only a small number of comparisons should be made, and the study should be designed to have an adequate sample size to reliably detect a clinically important treatment effect.[31-35] The comparisons to be conducted, as well as any specific subgroups of patients that will be considered separately, must be defined prospectively. Any imbalance in confounding baseline characteristics should be accounted for in the statistical analysis. Specific statistical tests are discussed later.

Step 9: Presentation and Publication of Results

Once the clinical trial data have been statistically analyzed, conclusions can be drawn from the results of the study. During the preparation of a manuscript describing the study and its conclusions, the investigators should be careful not to overextrapolate the results. Care should be taken to explain limitations in the study design and to enumerate factors that might bias the results of the study or at least limit its applicability to different patient populations. One purpose of the peer review process is to ensure that appropriate care is taken in interpreting the clinical trial results.

The enthusiasm of most investigators and clinicians for the results of a clinical trial is partly determined by the direction of the results.[36] For example, a trial that shows a highly effective new therapy for a serious disease is interesting and exciting. On the contrary, a trial that shows that a previously unstudied therapy has no advantage over the currently accepted treatment may be less interesting. Because positive results are inherently more interesting, it is commonly believed that clinical trials yielding positive results are more likely to be published than those with negative results. This effect is termed *publication bias*.[37-39]

However, studies have shown that trials with negative results may be less likely to be submitted for publication but, once submitted, are as likely to be published as trials with positive results.[37,39] Thus publication bias may be the result of a *file drawer problem,* meaning that study results that are negative sometimes end up in the file drawer instead of in manuscripts submitted for publication.[40]

Publication bias and the file drawer problem are serious threats to the validity of the medical literature taken as a whole. If negative trials are selectively excluded from the medical literature, an ineffective treatment may appear to be at least partially effective because those (possibly poorly designed) studies that show some positive treatment effect are selectively submitted for publication. Meta-analyses or systematic reviews often use only published research. It may be unethical to subject patients to the risks and discomforts of participation in a clinical study and not publish the results, especially if participation did not result in any direct benefit to the patient.

Publication bias and other sources of bias can be especially problematic in pharmaceutical or commercially sponsored clinical research. Commercial studies are less likely to report unfavorable conclusions.[41] Data from industry-sponsored research may go unpublished or may be difficult to obtain for subsequent review.[42] When reading a clinical trial, one should determine what agency or company funded the research and consider what biases, if any, might have been introduced.

DATA ANALYSIS

Classical Hypothesis Testing

Data from clinical trials are often analyzed by use of *P* values and classical hypothesis testing.[3,7,8] In classical hypothesis testing, two hypotheses that might be supported by the data are considered. The first, called the *null hypothesis,* states that no difference exists between the groups being compared with respect to the measured outcome of interest.[7] For example, in a study examining the use of a new sympathomimetic agent for blood pressure support in patients with sepsis, the null hypothesis might be that there is no difference between the average systolic blood pressure achieved with the test agent and that achieved with the control agent. The *alternative hypothesis* states that the average systolic blood pressure achieved is different in the groups being compared.[7] In this example study, the alternative hypothesis might be that the test agent results in a 10 mm Hg greater average systolic blood pressure than the control agent. The magnitude of the difference between the two groups defined by the alternative hypothesis is called the *treatment effect* (Tables 1 and 2).

Table 1 Steps in Classical Hypothesis Testing

STEP	DESCRIPTION
Define the null hypothesis	There is no difference between the groups being compared. For example, in a clinical trial, the null hypothesis might be that the response rate in the treatment group is equal to that in the control group.
Define the alternative hypothesis	The alternative hypothesis might be that the response hypothesis rate in the treatment group is greater than that in the control group by a given amount.
Calculate a *P* value	This calculation assumes that the null hypothesis is true. One determines the probability of obtaining the results found in the data or other results even more inconsistent with the null hypothesis. This probability is the *P* value.
Accept or reject the null hypothesis	If the probability of observing the actual data, or more extreme results, under the null hypothesis is small ($P < \alpha$), we should doubt that hypothesis. The idea is that if the probability under the null hypothesis of observing the actual results is very small, there is a conflict between the null hypothesis and the observed data, and we should conclude that the null hypothesis is not true.
Accept the alternative hypothesis	If we reject the null hypothesis, we accept the alternative hypothesis by default.

The treatment effect defined by the alternative hypothesis must be set before data are collected. The treatment effect should be large enough to be clinically important but small enough such that showing no difference between the groups rules out any clinically important treatment effect. In an interventional study, the difference defined is ideally the minimum treatment effect thought to be clinically significant (i.e., that which would lead to a change in clinical practice). Sometimes a larger treatment effect is defined because designing a study to reliably detect the smallest clinically significant treatment effect would require too large a sample size.[32-35] When evaluating the results of a clinical trial, one should look for the size of the treatment effect that the trial was designed to detect.

Once the null and alternative hypotheses are defined, the null hypothesis is "tested" to determine which hypothesis (null or alternative) will be accepted as true. The process of testing the null hypothesis consists of calculating the probability of obtaining the observed results or results that are even more inconsistent with the null hypothesis, assuming the null hypothesis is true. This probability is the *P* value.[7]

If the *P* value is less than some predefined value, denoted alpha (α; usually 5% or .05), the null hypothesis is rejected as false, and the alternative hypothesis is accepted as true. In other words, if the

Table 2 Terms Used in the Design of Clinical Trials

TERM	DEFINITION
Alpha (α)	Maximum *P* value to be considered statistically significant; the risk of committing a type I error
Alpha error	Type I error
Alternative hypothesis	Hypothesis considered an alternative to the null hypothesis; usually the alternative hypothesis is that there is an effect of the studied treatment on the measured variable of interest; also called *test hypothesis*
Beta (β)	Risk of committing a type II error
Beta error	Type II error
Null hypothesis	Hypothesis that there is no effect of the studied treatment on the measured variable of interest
Power	Probability of detecting a treatment effect the size of the treatment effect sought (i.e., obtaining a P value $< \alpha$), given alpha and the sample size of the clinical trial; power $= 1 - \beta$
P value	Probability of obtaining results similar to those actually obtained, if the null hypothesis were true
Type I error	Obtaining a statistically significant *P* value when, in fact, there is no effect of the studied treatment on the measured variable of interest; also called *false positive*
Type II error	Not obtaining a statistically significant *P* value when, in fact, there is an effect of the treatment on the measured variable of interest that is as large as or larger than the effect the trial was designed to detect; also called *false negative*

Table 3 Common Statistical Tests

STATISTICAL TEST	DESCRIPTION
Student's *t*-test	Used to test whether the means of measurements from two groups are equal, assuming that the data are normally distributed and that the data from both groups have equal variance
Wilcoxon rank sum test (Mann-Whitney test)	Used to test whether two sets of observations have the same distribution; similar in use to the *t*-test, but it does not assume the data are normally distributed
Chi-square test	Used with categorical variables (two or more discrete treatments with two or more discrete outcomes) to test the null hypothesis that there is no effect of treatment on outcome; assumes at least five expected observations of each combination of treatment and outcome under the null hypothesis
Fisher's exact test	Similar to chi-square test; it may be used even when fewer than five observations are expected in one or more categories of treatment and outcome
One-way analysis of variance (ANOVA)	Used to test the null hypothesis that three or more sets of continuous data have equal means, assuming the data are normally distributed and that the data from all groups have identical variances; may be regarded as a *t*-test for three or more groups
Kruskal-Wallis test	Nonparametric test analogous to one-way ANOVA; no assumption is made about normality of the data; may be regarded as a Wilcoxon rank sum test for three or more groups

null hypothesis were actually true, the probability of obtaining data like those obtained or even more extreme results by chance alone is less than alpha.

Type I Error

A type I error occurs when the investigator concludes that a difference has been demonstrated between two groups when no such difference exists.[7,8,43] It is a type of *false positive.* When data are analyzed by *P* values, a type I error occurs when a statistically significant *P* value is obtained but there is actually no underlying difference between the groups being compared. Because the *P* value is the probability of obtaining results equal to or more extreme than those actually observed, assuming there is actually no difference between the groups being compared, the risk of a type I error is equal to alpha, the maximum *P* value considered statistically significant, when the groups are fundamentally the same.[7,43]

Type II Error, Power, and Sample Size

A type II error occurs when a difference exists between the two groups and that difference is as great as that defined by the alternative hypothesis but a nonsignificant *P* value is obtained.[7,32-35] In other words, there really is a difference between the two groups, but the trial failed to demonstrate this difference. A type II error is a type of *false negative,* and the risk of a type II error is commonly denoted beta (β).

The *power* of a trial is the probability of detecting a treatment effect of a given size, if one truly exists.[32-35] Studies are usually designed to have a power of .80 or greater. Because the power of the trial is the chance of finding a true treatment effect, the quantity (1 − power) is the chance of missing a true treatment effect (i.e., risk of committing a type II error).[32,34] The value of $(1 - \beta)$, or the power, and the magnitude of the treatment effect the clinical trial is designed to detect (defined by the alternative hypothesis) determine the sample size required for the study.[35]

The smaller the size of the treatment effect the study is designed to detect, the larger the required *sample size* will be for a given value of alpha (the maximum significant *P* value) and for a given power. For any given treatment effect, a smaller maximum significant *P* value or a larger power will also require a larger sample size. Surprisingly, clinical studies are often published with negative results even though the studies did not have a sample size sufficient to reliably detect a clinically significant treatment effect.[32-35]

When reading a study, one should look for a statement about the power of the study. In general, a power of .80 or greater is desirable. The treatment difference tested should not be too large, such that smaller clinically important treatment differences may still exist even after a "negative" result. Power and sample size should be estimated before the study is begun; a "post hoc power analysis" after the data have been collected is not recommended.

Statistical Tests

Depending on the characteristics of the data being analyzed, different statistical tests are used to determine the *P* value (Table 3). Student's *t*-test and Wilcoxon rank sum test are used to compare continuous variables (e.g., serum glucose level and respiratory rate) between two groups of patients. If there are three or more groups of patients, one-way analysis of variance (ANOVA) and the Kruskal-Wallis test are used to compare continuous variables between the groups. The chi-square test and Fisher's exact test are used to detect associations between treatment and outcome

www.ketabpezeshki.com 66485457-66963820

when both the treatment and the outcome are categorical variables (e.g., placebo vs. active drug, lived vs. died, or admitted vs. discharged).

Student's *t*-test and one-way ANOVA are examples of parametric statistical tests. Parametric tests make assumptions about the underlying distribution of continuous variables. Both Student's *t*-test and ANOVA assume that the data are normally distributed (i.e., distributed in a bell-shaped curve around the central mean) and that the different groups yield data that have equal variance.

When the data to be analyzed are not normally distributed, the *P* value should be obtained by use of a nonparametric test.[7,8,44] Nonparametric tests are distribution free in that they do not rely on the data to have any particular underlying distribution. The nonparametric alternative to a *t*-test for unpaired samples is the Mann-Whitney U test, or Wilcoxon rank sum test. For a statistical comparison of paired measurements, the Wilcoxon signed rank test can be used. The nonparametric alternative to one-way ANOVA is the Kruskal-Wallis test. The *t*-test may be used inappropriately when the data are unlikely to be normally distributed. If it is unclear whether the data are normally distributed, it is preferable to use the nonparametric test.

Confidence Intervals

Often, the primary goal of a clinical trial is not simply to obtain a yes or no answer to the question of whether a treatment has any efficacy at all but rather to estimate the magnitude of the treatment effect. This goal of measuring the effect of the treatment arises if another treatment is known to be effective. On the other hand, if no effective treatment is available, a new therapy may be adopted even if the study shows only the possibility of effectiveness.

When the primary goal of a study is to measure or to estimate a treatment effect, the results should be reported by use of confidence intervals.[45-49] In general, a *confidence interval* is a range of possible values for a treatment effect that are statistically likely given the results of the current trial. For example, a 95% confidence interval is likely to contain, within its limits, the true size of the treatment effect 95% of the time.[48,49] Confidence intervals are easily calculated for most data.[49] Advanced statistical methods may be required to report confidence intervals for data with non-straightforward (e.g., normal or binomial) distributions.[50]

Situations may arise in which a *P* value and confidence interval can lead to different qualitative interpretations of the same clinical trial results. Suppose one is studying a treatment for a disease that has no known effective therapy. If the 95% confidence interval for the treatment effect ranges from −2 to 30%, where the treatment effect is measured as the change in the absolute percentage of patients with a good outcome, many clinicians would interpret this as showing that although the therapy may have little benefit, it has the possibility of having significant benefit (improving the outcome for up to 30% of patients). Thus many clinicians would adopt the therapy as appropriate, given the lack of an effective alternative. If classical hypothesis testing had been used to analyze the same data, a nonsignificant *P* value would have been obtained. Many clinicians would then interpret the study as failing to show efficacy and conclude that the therapy is not appropriate for clinical use.[45-49]

When reading a study, one should look beyond the *P* values to the size of the treatment effect found and the width of the confidence intervals. If *P* is reported as significant (usually < .05), one should make sure that the difference is clinically significant. For example, a difference in reduction of temperatures by 0.5° C between two antipyretics may not be clinically significant but would be statistically significant in a sufficiently large study. Issues such as cost, palatability, and adverse effects are likely to be more important in choosing between the two antipyretics. If *P* is reported as not significant (usually > .05), the practitioner should ensure that the confidence interval is not so wide that a clinically important treatment effect is still possible, as in the previous example.

Multiple Comparisons

Whenever two groups of patients are compared statistically, even if they are fundamentally identical, a statistically significant *P* value can be obtained by chance.[7,43] If the maximum significant *P* value (alpha) is .05, there is a 5% chance that a statistically significant *P* value will be obtained when no true difference exists between the two patient populations. This risk of a false-positive *P* value occurs each time a statistical test is performed. When *multiple* comparisons are performed, whether they are "pairwise comparisons" of more than two groups of patients or the comparison of many different characteristics between two groups of patients, the risk of at least one false-positive *P* value is increased because the risk associated with each test is incurred multiple times (Table 4).[31,51,52] For a small number of tests, the overall risk of at least one type I error is roughly equal to the maximum significant *P* value used for each individual test multiplied by the total number of tests performed. This rough equality is the basis for the Bonferroni correction.[7,11,31]

The *Bonferroni correction* is a method to reduce the overall type I error risk for the whole study by reducing (i.e., making more stringent) the maximum *P* value used for each of the individual statistical tests ("testwise risk"). The desired overall risk of a type I error (usually .05) is divided by the number of statistical tests to be performed, and this value is used as the maximum significant *P* value for each individual test. For example, if five comparisons are to be made, a maximum significant *P* value of .01 would be used for each of the five statistical tests.

The Bonferroni correction controls the overall risk ("studywise risk") of a type I error at the expense of an increased risk of a type II error. Because each statistical test is conducted with a more stringent criterion for a statistically significant *P* value, there is an increased risk that each test might miss a clinically important difference and yield a *P* value that is nonsignificant with the new criterion of *P* < .01.

Specific statistical tests have been developed to compare three or more groups of patients, such as one-way ANOVA, Kruskal-Wallis test, chi-square test, and Fisher's exact test (see Table 3). These tests, which do not use the Bonferroni correction, can be useful for detection of differences among three or more groups with relatively high power while controlling the overall risk of a type I error. Their disadvantage is that although they can detect a

www.ketabpezeshki.com 66485457-66963820

difference among three or more groups of patients, they do not define *which* pairwise differences are statistically significant. When reviewing positive studies with multiple study groups or multiple comparisons, one should consider the potential for an increase in type I error and check for the use of statistical methods accounting for multiple comparisons or appropriate for more than two study groups.

Interim Analyses of Accumulating Data

During a clinical trial, data accumulate sequentially and contain increasingly more information on the effectiveness of the treatments being compared. Often, however, these data are not analyzed until the trial has been completed and all patients have been enrolled. This type of fixed sample size design has the disadvantage of possibly enrolling more patients than are necessary to obtain a reliable result, either positive or negative. It is often advantageous to plan one or more *interim analyses* of the data to be conducted before the full sample size has been reached to determine whether a reliable conclusion can be drawn from the data and the trial terminated early. Because this is a type of multiple comparison, such interim analyses must be planned in advance to avoid increasing the risk of a type I error.[11,52-54] When reading a study reporting results of an interim analysis, one should look to see that the interim analysis was planned and not performed because a casual observation of the data showed interesting or promising results.

Subgroups

Any group of patients is heterogeneous; this is especially true for groups of patients defined by presenting signs and symptoms in an emergency department setting. Some of the patients within such a group may have a more severe form of the disease in question, and some patients may have a coexisting disease that modifies the original disease process. Almost any group of patients can be considered to have multiple *subgroups,* each of which is more homogeneous than the overall group.

Because of this heterogeneity, a treatment effect that is detected within the entire group may or may not exist for a particular subgroup of the original population, or vice versa.[55-57] Therefore, the data from subgroups of patients are often analyzed separately. In some circumstances, this is important in determining which therapies are most effective in clinically important subgroups of patients.[55,56]

When subgroups of patients are to be analyzed, they should be defined prospectively. Unfortunately, studies with an overall negative result may emphasize a positive treatment effect found only in a subgroup defined after data collection. Although such findings may warrant brief discussion and further investigation, they are unreliable because analysis of data from all possible after-the-fact subgroups requires the use of multiple statistical comparisons, which increases the chance that the finding represents a type I error, or false-positive result.

Even if the subgroups are defined before the acquisition of any of the clinical trial data, testing for a treatment effect in each subgroup potentially increases the risk of a type I error. Also, because each subgroup of patients is smaller than the entire study population, the analysis of these subgroups may have low statistical power, which increases the chance of a type II error.

Additional problems can occur if the subgroups of patients are not defined properly.[55,56] A "proper" subgroup of patients is defined by signs, symptoms, or laboratory results that are available at the initial presentation and that are not modified by the treatments being compared. An "improper" subgroup of patients is defined by signs, symptoms, or laboratory findings that can, in principle, be modified by the treatments being administered. For example, in a study that compares different volumes of fluid resuscitation for patients with septic shock, an improper subgroup of patients might be defined by a low systolic blood pressure after fluid administration (the so-called refractory shock group). Conversely, a proper subgroup would be defined by a low systolic blood pressure before any fluid administration.

Because of the possible association between the subgroup assignment and the treatment being administered in an improperly defined subgroup, improper subgroups cannot be used to assess the effectiveness of therapies. It is a common error in many retrospective studies to compare such improper subgroups of patients. When reading a study reporting results in subgroups of patients, one should look to see that the subgroups were prospectively and properly defined and consider whether the characteristics defining the subgroup would be known during emergency department care.

Multivariate Models

Multivariate modeling is a statistical tool used to determine the association between two or more independent (predictor) variables and a single dependent (outcome) variable. For example, a multivariate model might be used to determine the simultaneous effects of the patient's age and initial systolic blood pressure on the patient's chance of survival after penetrating abdominal trauma.

The two most common types of multivariate models in medical literature are multivariate linear regression models and multivariate logistic regression models. *Linear regression models* are used to determine the effects of two or more variables on a continuous outcome variable, such as blood pressure. *Logistic regression models* are generally used when the outcome is binary, such as survival (lived vs. died) or admission to the hospital (admitted vs. discharged).

Multivariate models offer several advantages over univariate analyses.[58-60] In a *univariate analysis,* the effect of a single predictor on the outcome is studied in isolation, often with the statistical tests discussed previously. Multivariate models are more akin to "real-life" clinical decision-making, whereby a clinician considers several factors, such as demographics (e.g., age and gender), history elements, and physical examination findings, in deciding a patient's likely diagnosis or clinical course. They can determine which subsets of variables have significant effects on the outcome.

Multivariate models allow one to control for *confounders,* variables associated with the predictor one wishes to study that may also affect the outcome. For example, in studying the effect of alcohol intake on the outcome of lung cancer diagnosis, tobacco smoking may confound the findings because patients with high alcohol intake are more likely to also smoke, and smoking increases lung cancer. A multivariate model that includes both predictors, alcohol intake and smoking, allows one to look at the isolated effect of alcohol intake while holding the effects of other predictors (smoking) constant.[58]

An example of this phenomenon was illustrated in a study of the predictors of mortality in patients with ruptured abdominal aortic aneurysms.[61] Univariate analysis did not reveal the emergency department–to–operating room time interval to be a significant predictor of mortality, whereas in the multivariate model, prolonged emergency department–to–operating room time was clearly a significant predictor. Patients with longer emergency department–to–operating room times probably presented with other findings that made their diagnosis less clear, or the need for intervention appear less urgent, and that were also associated with improved survival, such as higher initial systolic blood pressure and higher hemoglobin concentration. In the multivariate model, the effect of emergency department–to–operating room time

www.ketabpezeshki.com 66485457-66963820

could be assessed while holding such confounders as initial blood pressure and hemoglobin concentration constant.

The disadvantage of multivariate modeling is that it is more complex than univariate analysis. Certain statistical assumptions must be met, such as normal distribution of the outcome. Sometimes a single data point with an extreme value for a predictor or outcome variable, termed an *outlier,* exerts undue effects in the model. Regression diagnostics should be performed to assess that the statistical assumptions have been met and that no outliers are exerting undue effect.[58]

If two or more predictor variables interact (e.g., alcohol intake exerts an effect only in men, and not women, so that gender influences the effect of alcohol intake), an *interaction term* must be included in the model. If two or more predictor variables give redundant information (e.g., the predictors age and arrest etiology may give redundant information for the outcome survival from pediatric cardiopulmonary arrest because most infants have an arrest etiology of sudden infant death syndrome), the predictors are said to have *multicollinearity,* and this may require revision of the model (e.g., removal of one or more predictors).[58]

Authors should report statistics that measure the *goodness of fit,* or how well the model explains the observed data. However, the model may display good fit with use of these statistics and still be missing an important predictor variable or contain more predictor variables than necessary. Ultimately, investigators and readers need to have a basic understanding of the disease under study to determine that all the likely significant predictors have been accounted for in the model.[58]

When reading studies using multivariate models, one should look for the use of independent predictor variables that make clinical sense. One should check for the reporting of statistics measuring goodness of fit as well as discussion of regression diagnostics performed.

Importance of Prior Probabilities

On occasion, statistical tests yield surprising results. Unexpected results are especially difficult to interpret by classical hypothesis testing. Consider a clinical trial that uses a randomized, double-blind controlled design to compare two antibiotics for prophylaxis of infectious complications of tube thoracostomy, with the development of local wound infections or empyema as the primary endpoint. Suppose no statistically or clinically significant difference is found in the rate of infectious complications, but a statistically significant difference in mortality is noted between the two treatment groups ($P = .03$). It seems inherently unlikely that the choice of prophylactic antibiotic would affect survival without affecting the infection rate. This is an example in which the apparent conclusion of the trial has a very low *a priori probability* of being true. In other words, the a priori probability that the choice of prophylactic antibiotic could influence survival after traumatic injuries without affecting infection rates is exceedingly small.

Two possible explanations exist for such results. First, the antibiotic may have a true effect on survival by a previously unknown mechanism. The results of the trial would then be a true positive. Second, the results of the study might represent a type I error, with the statistically significant *P* value occurring by chance, even though the antibiotic has no effect on survival. The second explanation seems more likely than the first because the chance that the antibiotic exerted its effect through a previously unsuspected mechanism is small. Thus, despite the fact that a statistically significant *P* value was obtained, it is unlikely that a true treatment effect exists. Classical hypothesis testing is most likely to be misleading when the alternative hypothesis being tested has a very low a priori probability of being true.[62]

The chance of any particular interpretation of data being correct depends both on the a priori probability of that conclusion's being true and on the data supporting that conclusion.[62] An entire branch of statistical reasoning, Bayesian statistics, has been developed to incorporate a priori information quantitatively into the interpretation of data. Bayesian analysis is analogous to usual clinical reasoning in which laboratory test results are interpreted in light of the patient's underlying risk of disease.[62,63] For example, the proper interpretation of nonspecific T wave abnormalities in an electrocardiogram (ECG) depends on the patient from whom the ECG is obtained. If the ECG is obtained from a patient with multiple cardiac risk factors and typical ischemic chest pain, the T wave abnormalities should be considered suggestive of myocardial ischemia. If, on the other hand, the ECG is obtained from a young, healthy adolescent with a very low chance of having cardiac disease, the T wave abnormalities should be considered a normal variant. This use of a priori risk of disease in interpreting data is common in clinical practice. Similar logic should be used in the interpretation of data from a clinical study, especially when the conclusion would have been considered very unlikely before the study was performed.[62-64]

When reviewing studies, one should consider the results in the context of one's knowledge base. Is there scientific basis for the results? Are the results in congruence with other research in this area? Have the results been corroborated in subsequent studies?

Data Dredging or Torturing

It is surprisingly common for large databases containing many hundreds or even thousands of patient records to be created without clear prior definition of what questions are to be asked of the data. A typical example of this type of database is a trauma registry. When such databases are analyzed, the number of different questions that could be asked (or hypotheses tested) is enormous. In the case of a trauma registry, many tens of variables potentially associated with an adverse outcome are collected. It is tempting to test statistically for an association of each of these variables with survival in an attempt to find combinations of variables that predict outcome. When such exploratory data analyses are performed without clearly defined hypotheses, the analyses may entail a very large number of statistical tests. Each one of these statistical tests carries the risk of a type I error. If enough hypotheses are tested, one is virtually assured of obtaining some statistically significant *P* values, even if none of the variables are truly associated with outcome.

Multiple comparisons are also made, although only implicitly, when large collections of data are visually inspected by an investigator searching for trends or associations. The investigator may make dozens of mental comparisons, most of which show little obvious difference among the groups being compared. Often, however, some "interesting" differences are noted and brought to the attention of the statistician for statistical testing. The statistician may then find a statistically significant difference but is unaware that many comparisons were made by the investigator in searching for one or a few promising comparisons.

This process of making a large number of implicit or explicit comparisons in searching for possibly important differences is called *data dredging* or, more pejoratively, *data torturing.*[65] Such undirected analyses of large databases virtually always yield statistically significant *P* values that are meaningless. Thus, even when working with large collections of data, it is essential that the comparisons to be made are defined before the inspection or collection of the data and that the total number of comparisons is kept to a minimum. The risk of false-positive results from data dredging is especially high when the hypotheses tested were unlikely to have been chosen before the data collection. In other words, hypotheses that are motivated by the same data used to test them are much less likely to be true than hypotheses that are

www.ketabpezeshki.com 66485457-66963820

defined before the data collection, based on independently known associations or concepts.

Not all studies performed on large preexisting databases are examples of data dredging. When reviewing such studies, one should look to see that the hypothesis was defined before any manipulation of the database. The hypothesis should be based on independent observations and corroborated by previous research (basic science, animal, or clinical).

Intention-to-Treat Analysis

The effectiveness of any therapy is determined both by the therapy's inherent efficacy and by the emergency physician's ability to administer the therapy to the patient. For example, in the case of an oral medication, the effectiveness will be decreased if patients find the medication's side effects to be intolerable and are noncompliant. Similarly, an invasive procedure will be less effective, on average, if it can be performed successfully only in a minority of patients. To estimate accurately the effectiveness a therapy will have in clinical practice, the emergency physician should properly account for those patients for whom a treatment is initiated but cannot be completed. This is the purpose of an intention-to-treat analysis.[66]

In an *intention-to-treat analysis,* patients are considered to be members of the treatment group to which they were originally assigned, regardless of whether they take the prescribed medication or the appropriate therapy is successfully administered to them.[66] For example, in a trial that examines the use of an oral agent, patients would be considered to be part of the test group if they were originally prescribed the test medication, even if they freely admit to never having taken any of the tablets.

In a study of out-of-hospital intubation, children were randomized to receive bag-valve-mask (BVM) ventilation alone or BVM ventilation followed by endotracheal intubation (Fig. 2).[67] The populations of children were inherently heterogeneous; some children had sudden infant death syndrome, and others had closed head injury. The initial population was well randomized to the two interventions. Children with sudden infant death syndrome were substantially easier to intubate (because of their flaccid state) in the out-of-hospital setting than children with closed head injury, but their overall survival rate was much lower.

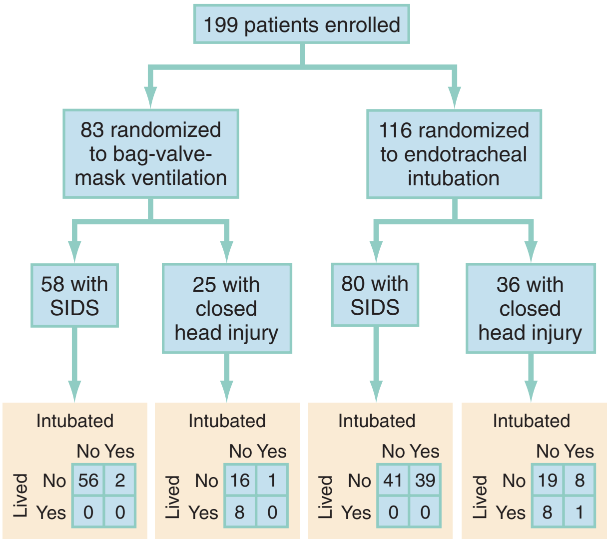

Figure 2. Results from a clinical trial comparing the use of bag-valve-mask ventilation with the use of endotracheal intubation in patients requiring advanced airway management in an out-of-hospital setting. *SIDS,* sudden infant death syndrome.

The goal of the analysis of the data was to determine the effect of out-of-hospital endotracheal intubation on survival. The correct way to group the data is to consider all patients initially assigned to the endotracheal intubation group as belonging to that group, whether or not they were successfully intubated. Thus, of 199 patients, 116 patients were assigned to the endotracheal intubation group and 83 patients were assigned to the BVM ventilation group. Considering all patients in the endotracheal intubation group, whether or not they were successfully intubated, the overall survival rate is 7.7% (9/116). Similarly, considering all patients in the BVM ventilation group, the overall survival rate is 9.6% (8/83). Thus the results of the study show a small trend toward improved survival with BVM ventilation.

Alternatively (but incorrectly), one might group the data according to the treatment actually received (*by treatment received analysis*).[66] In this case, children initially assigned to the endotracheal intubation group but not successfully intubated might be considered to be members of the BVM ventilation group because that was the treatment they actually received. If one counts all children who received only BVM ventilation, the overall survival rate in that group is 10.8% (16/148). Similarly, if one considers only children who were *successfully* intubated as the members of the endotracheal intubation group, the overall survival rate in that group is only 2.0% (1/51). This is because more children with sudden infant death syndrome are successfully intubated as a result of their flaccid state, but these children have lower survival rates. Similarly, children with closed head injury may be more combative and difficult to intubate but have higher survival rates than those with sudden infant death syndrome. This type of analysis then suggests that endotracheal intubation is extremely harmful. Whenever there is an association between compliance or the ability to administer an intended treatment and the patient's baseline chance of a successful outcome, analysis by treatment received does not accurately estimate the effect of the therapy in an actual patient population.

Even when an intention-to-treat analysis is used to analyze study results, extrapolation of the results to the general population may be unreliable if the compliance in the general population is lower than that in the study population.[68] This is a common problem because study populations tend to be more compliant than the general population. When reviewing a study, one should look for an intention-to-treat analysis rather than analysis by treatment received. In addition, one should assess whether one's patient population is likely to be as compliant as the study population or, in the case of a procedure, whether one is likely to be able to perform the procedure with the same rate of success.

Meta-analysis

Meta-analysis, or systematic review, is a statistical method for quantitatively combining the results of multiple clinical trials that investigate identical or similar therapies for a specific disease to obtain more accurate estimates of the effectiveness of the treatment.[69] Unlike the traditional review article, a meta-analysis emphasizes the quantitative estimation of the treatment effect observed in all the available studies taken as a whole and usually provides an estimate of the reliability or quality of the results of each study. Meta-analyses can be powerful tools in practicing evidence-based medicine because they collate the results of many or all available studies.[70]

Studies with poor design have been shown to be more likely to find an apparent positive treatment effect. A meta-analysis that includes many poorly designed studies tends to bias the results toward showing a positive treatment effect, even if no such effect exists. Methods for controlling and measuring the effect of poorly designed studies on the results of the meta-analysis have been developed and are often termed *sensitivity analyses*.[71] One method

www.ketabpezeshki.com 66485457-66963820

is to first perform the meta-analysis using only studies of the highest quality and then to sequentially include studies of increasingly lower quality to determine whether this causes a directional shift in the results. This approach requires a relatively objective measurement of study quality. Numerous scales and methods to define study quality have been developed.[72,73]

Publication bias, whereby smaller studies with negative results (i.e., no treatment effect shown) are not submitted for publication, may affect the validity of the conclusions drawn by a meta-analysis.[70] Authors of meta-analyses must strive to include all available trials, often requiring search strategies beyond a simple MEDLINE search. Other methods may include hand searching of relevant review articles and identified studies' reference lists, contacting of commercial sponsors and investigators to seek unpublished data, and searching of nontraditional bibliographic databases.[74] Problems can arise when pharmaceutical companies withhold data from commercially sponsored trials.[42] Requirements for all clinical trials to be entered into registries at the time of initiation may help alleviate problems associated with unpublished data.

Funnel plots are used to assess for publication bias.[71] Authors plot trial size or quality score against treatment effect. One would expect a funnel-shaped plot, whereby smaller and lower quality trials have a wide base centered around the mean treatment effect, whereas larger and higher quality studies, because they provide more accurate estimates of the treatment effect, make up the narrower top of the funnel. If a portion of the funnel is missing, such as the smaller studies with no treatment effect, this is indicative of publication bias.

Sometimes discrepancies arise between meta-analytic results and subsequent results from a large randomized clinical trial, leaving the reader wondering which results are correct.[75] Discrepancies may be due to bias introduced in the meta-analysis because of poor quality of studies included or publication bias.[75,76] Discrepancies may also be due to differences in inclusion or exclusion criteria or in definitions of outcomes. For example, a meta-analysis of studies that included patients at high risk for preeclampsia found calcium supplementation to be effective prophylactic therapy, whereas a single large trial that included only low-risk patients found calcium supplementation to have no effect.[77] Because of the inclusion of multiple trials, a meta-analysis may incorporate results from thousands of patients, and small treatment effects may reach statistical significance. Such small treatment effects may be false positives arising from inadvertent bias in poorly designed studies or from an artifact of the meta-analysis. Alternatively, the results may be true but clinically unimportant, or they may be true, clinically important, and warrant a change in clinical practice. The discerning reader considers the size of the treatment effect and possible bias introduced by the meta-analysis methodology and studies included to determine which of the previous conclusions is most likely.

When reviewing a meta-analysis, look for (1) assessment of the quality of trials included, (2) comprehensiveness of the search strategy for studies to be included and assessment of possible publication bias, (3) narrow confidence intervals indicating a large number of patients, and (4) agreement of the majority of the highest quality studies with the overall conclusion. Even when results are statistically significant, consider whether the size of the treatment effect is clinically significant and, combined with consideration of the costs and risks of the therapy, warrants a change in clinical practice.

CHANGING PRACTICE ON THE BASIS OF A RESEARCH STUDY

After reading the publication of results from a clinical research study, clinicians must decide whether the results of the study should cause them to change their clinical practice. There are several factors to consider in making this decision, the most obvious being the quality of the study and the results themselves. Other factors to consider include the context of the study within the available literature; the similarity of the clinician's practice setting and the clinician's likely ability to achieve results similar to those in the study; and the risks, benefits, and costs of changing clinical practice.[78]

For the clinician to change clinical practice on the basis of the results of a study, first the study must be high quality. In general, well-done systematic reviews of multiple randomized clinical trials provide better evidence than a single randomized clinical trial, and randomized clinical trials provide better evidence than observational or cross-sectional studies, while recognizing that some clinical questions do not lend themselves to randomized interventional trials. Also in general, prospective studies provide higher quality information than retrospective studies (e.g., chart review studies). Table 5 summarizes key study characteristics to look for in the evaluation of research studies. The CONSORT statement provides a helpful framework to evaluate the quality of a research trial and the written report of the trial's results and is required by many medical journals. It includes both a checklist of important study design information that should be provided for the reader and a flow diagram tracing patient enrollment, treatment allocation, follow-up, and analysis (www.consort-statement.org). The flow diagram is particularly valuable for verification that patients received the treatments they were assigned and that few if any subjects were lost to follow-up.

Once the study is determined to be of sufficient quality to believe that the results are valid, those results should be interpreted in the context of related medical literature and experience. The next section of this chapter reviews evidence-based medicine principles to be used in gathering and evaluation of evidence from the medical literature. If the current study is an outlier in its conclusions and equally high-quality studies in the literature do not support changing clinical practice, the clinician should consider waiting for further evidence. Expert guidelines and editorials may help the clinician weigh the available evidence and consider possible causes of differing results between studies.

The clinician should decide whether the study's patient population and health care practice setting are similar enough to the clinician's to make the study results relevant to the clinician's practice (a type of external validity). A study performed in a population from the East Coast demonstrating Lyme disease to be a common cause of meningitis may not be relevant to a clinician practicing in an area with low prevalence of Lyme disease. A study showing the utility of a particular intervention applied within 60 minutes of the patient's onset of symptoms may not be relevant to a clinician who works in a health care setting that is unable to provide that intervention in the same time frame (e.g., because of delayed patient presentations). The study's inclusion and exclusion criteria should be closely examined to determine whether the clinician's patient population sufficiently matches the study population, and the study protocol should be examined to determine whether the clinician would be able to provide similar care. Often, simply by virtue of being a research study protocol with the added advantages of having research personnel focused on patient enrollment and study completion, compliance and follow-up are better than in a typical clinical setting.

Finally, the clinician should perform an informal cost analysis before changing clinical practice. If an intervention is extremely costly, even if it was shown unequivocally to provide some benefit, the costs may outweigh the benefits. Costs may not necessarily be only financial, such as potential adverse effects and "opportunity costs," whereby receipt of one therapy results in the loss of the opportunity to receive another proven therapy or requires hospitalization. Clinical practice should be changed only when, on

Table 5 Checklist to Assess Quality of Research Studies

Longitudinal Interventional Study (Clinical Trial)	
Study population	Inclusion and exclusion criteria are well defined, identify a population large enough to be clinically important, and can be applied in the emergency department setting
Enrollment	Enrollment as complete as possible (e.g., consecutive patients meeting enrollment criteria) Missed patients accounted for and not systematically different from study participants (selection bias)
Controlled	Control group similar to intervention group except for treatment received (usually requires randomization) Contemporaneous (not historical) control group
Randomized	Truly randomized allocation of treatments Study personnel unable to influence treatment group assignment Blinded assignment to treatment groups (patients, clinicians, and study personnel all blind to treatment group)
Outcomes	Important potential confounders measured and accounted for by randomization or statistical analyses High compliance with treatments between study groups Small number of patients lost to follow-up and patients lost to follow-up are not systematically different between study groups or different from those not lost to follow-up Appropriate, clinically relevant outcome definitions Those determining outcomes blinded to treatment group allocation Outcome difference between groups clinically significant as well as statistically significant Uncertainty in outcome difference quantified by use of confidence intervals or similar methods
Statistical analysis	Correct statistical procedure used (see Table 3) Treatment effect to be detected established a priori Sample size calculation performed before study is started Intention-to-treat analysis performed (patients analyzed in the groups to which they were originally assigned, despite actual treatment received)
Conclusions	Limitations and potential biases explained Conclusions not overextrapolated outside study population or study protocol
Additional Considerations	
Multiple comparisons	If multiple groups were studied or multiple comparisons were made, appropriate statistical procedures to account for this were used Interim analyses were planned a priori and conducted according to plan
Subgroups	Subgroups reported were defined before beginning of the study (prospectively defined) and limited in number If multiple subgroups studied, statistical procedures are used to account for multiple comparisons or the number of subgroups is small Adequate sample size in important subgroups Subgroups defined by characteristics available to the clinician at initial presentation (proper subgroups)
Multivariate models	Independent predictor variables included in the model make clinical sense and include all important variables "Goodness of fit" statistics reported and regression diagnostics performed
Meta-analysis or systematic review	Comprehensive search strategy used to identify potential trials to be included Quality of trials assessed Sensitivity of results to exclusion of lower quality studies assessed Funnel plot used to assess publication bias Narrow confidence intervals indicate a large number of patients Majority of highest quality studies agree on overall direction of treatment effect

balance, the potential benefits outweigh the costs. This cost-benefit analysis may differ according to patient population, health care system, and individual circumstances.

EVIDENCE-BASED MEDICINE

Evidence-based medicine (EBM) refers to the systematic gathering of information from the medical literature, often regarding the effectiveness of a particular treatment or the diagnostic accuracy of a particular test, with the intent to apply that evidence in diagnostic or management decisions related to an individual patient.[79,80] Although a specialized vocabulary has evolved, including both old and new terms (Table 6), the practice of EBM essentially involves the systematic application of long-established principles of medical literature analysis that until recently were often unknown by or impractical for the medical practitioner.

The fundamental steps in EBM are (1) to define precisely the clinical question being asked in terms that can be addressed by clinical studies; (2) to gather the available medical literature related to the question defined; (3) to assess the relevance, validity, and quality of the evidence contained in each study; and (4) to summarize the available evidence so that diagnostic and management decisions can be made for the individual patient on the basis of the recovered information.[79]

Step 1: Definition of Clinical Question

The first step in the practice of EBM is to define the clinical question clearly. The process of developing a well-formulated clinical question consists of several parts. First, the practitioner should define the population of patients similar to the individual patient motivating the search. The goal is to define a group of patients broad enough that they are likely to have been studied in clinical trials but specific enough that they are similar to the patient. Second, the practitioner should define the treatments or diagnostic approaches being considered. This involves defining the alternative approaches that might be used by reasonable practitioners in similar situations. Third, the practitioner should define the outcome of interest. The outcome of interest should be important to the patient and definable in terms of measurable quantities.

www.ketabpezeshki.com 66485457-66963820

Table 6 Terms Used in Evidence-Based Medicine

TERM	DEFINITION
Bias	Tendency to yield a result that lies to one side or the other of the true value; an error that is not centered around zero
Critically appraised topic (CAT) or best evidence topic (BET)	Summary of the results of an analysis of the evidence relevant to a particular clinical question
Likelihood ratio, negative (LR–)	Probability that a negative test result would occur in a patient with the disease in question divided by the probability that a negative test result would occur in a patient without the disease in question (generally < 1)
Likelihood ratio, positive (LR+)	Probability that a positive test result would occur in a patient with the disease in question divided by the probability that a positive test result would occur in a patient without the disease in question (generally > 1)
Negative predictive value	Fraction of patients with a negative test result who, in fact, do *not* have the disease in question
Number needed to treat (NNT)	Number of patients who must be treated with the better of two treatments so that one additional "good" outcome is obtained
Odds	Probability of an outcome divided by the probability of the outcome not occurring
Odds ratio	Odds of the outcome of interest occurring in one group of patients divided by the odds of the outcome of interest occurring in another group
Positive predictive value	Fraction of patients with a positive test result who, in fact, *do* have the disease in question
Post-test odds	Odds of the outcome of interest (e.g., particular disease being present), once a particular test result (positive or negative) is known to have occurred; equal to the pretest odds times the likelihood ratio for the test result obtained
Post-test probability	Probability of the outcome of interest once a particular test result is known to have occurred
Pretest odds	Odds of the outcome of interest before the test result is known
Pretest probability	Probability of the outcome of interest before the test result is known
Relative risk	Probability of an outcome in one group divided by the probability of the same outcome in another group
Reliability	Degree with which a clinical trial or diagnostic test is likely to yield consistent results when repeated
Sensitivity	Fraction of patients with the disease in question who have a positive test result
Specificity	Fraction of patients without the disease in question who have a negative test result
Validity, external	Degree to which the results from a study accurately reflect what would happen to similar patients who were not enrolled, including patients at other locations
Validity, internal	Degree to which a study accurately measures the outcomes for the enrolled study population

The steps required to define the clinical question in EBM practice are similar to the steps required to define a good hypothesis for a clinical trial: (1) the population for a clinical trial should be clearly defined, (2) the interventions to be used should be reasonable and well defined, and (3) one or at most a few clinically relevant and measurable outcomes should be defined.

Step 2: Collection of Evidence

The second step in the practice of EBM is to gather the available evidence.[79,81-84] Although a variety of resources might be used to accomplish this, the practitioner generally begins by searching one of the available electronic databases of published medical literature (e.g., MEDLINE). In addition, the physician may want to search one of the databases of known clinical trials (e.g., Cochrane Collaborative) because these databases often include the results from studies that have not been published or are not available on MEDLINE. Initially, the goal is to cast a wide net to gather as many of the available studies as possible.[79]

Step 3: Analysis of Studies for Validity, Reliability, and Relevance

The third step in the practice of EBM is to analyze each of the gathered studies to determine its validity, reliability, and relevance. The *validity* of a study is the degree to which the results are likely to represent "truth." When the clinical question involves the effect of a therapeutic intervention, a double-blind, randomized clinical trial is generally believed to be the most valid type of study. The *external validity* of a study may be reduced if the patient population in the study is too dissimilar to the patient motivating the current activity or if the clinical setting is substantially different from the physician's practice setting. Threats to *internal validity* include inadequate blinding, inadequate or no randomization, and use of historical controls or, worse, absence of controls.

The *reliability* of a study refers to the degree to which the results of the study are likely to be the same if the study were repeated in the same clinical setting with another group of similar patients. A study may have reduced reliability if the sample size is too small or if some of the study procedures were poorly defined and therefore difficult to repeat consistently (e.g., if some interventions were decided by individual treating physicians).

The *relevance* of a study is the degree to which the results, specifically the outcome or outcomes measured, directly address the clinical question being posed. Thus a study is less relevant if the outcome used in the study is different from the outcome deemed most clinically important. For example, long-term survival may be the most clinically important endpoint for a particular condition, whereas the available clinical trials may use survival at 24 hours as their endpoint. This leaves open to question whether

www.ketabpezeshki.com 66485457-66963820

differences observed in survival at 24 hours would lead to differences in long-term survival.

Step 4: Summary of Most Useful Evidence

On the basis of these considerations, the practitioner of EBM proceeds to the fourth step, summarizing the available evidence from the studies that are the most valid, reliable, and relevant. For each of these studies, the size of the treatment effect or the accuracy of the diagnostic strategies should be noted. In the case of a binary outcome (e.g., lived vs. died or admitted vs. discharged), the *number needed to treat* is a useful measure of the size of the treatment effect.[80] The number needed to treat is the number of patients that must receive the treatment for every one patient who benefits as per the outcome defined in the study. Other useful measures of the size of the treatment effect include the odds ratio and the relative risk. The utility of diagnostic tests is best measured by positive and negative likelihood ratios. Other useful measures of diagnostic accuracy include sensitivity, specificity, positive predictive value, and negative predictive value.[85-87]

Step 5: Application to Patient and Critical Appraisal

Once the available evidence from high-quality studies is summarized, the practitioner is ready to apply the information to the care of the individual patient. To save the information, however, it is useful to create a summary of the entire EBM process, briefly describing each step and the results from each step. Such summaries are sometimes called *critically appraised topics* or *best evidence topics* (CAT or BET), which can be saved for future reference.[88] Such "shortcut reviews" performed by others are available in journals or online (http://ebem.org/index.php), but results should be interpreted in light of the specific study question, the comprehensiveness of the search for evidence, and the appraisal process used.[89]

Effectiveness of Evidence-Based Medicine

With the rapid expansion of clinical research, it is difficult to keep EBM reviews up to date. Also, for clinicians to find reviews useful in real-time patient management decisions, reviews should be easily and rapidly accessible. This adds another layer of difficulty for EBM to have an impact on clinician behavior. EBM techniques may be applied to create clinical guidelines and algorithms, which when disseminated may have a greater effect on clinician behavior. There is, however, little research studying the effectiveness of various presentations of EBM reviews on clinician behavior or patient outcomes.[90]

SUMMARY

For the educated reader, the medical literature provides an ever-expanding view of knowledge regarding the effectiveness of medical therapy. A qualitative understanding of the concepts described in this chapter allows the emergency physician to distinguish high-quality studies with results that warrant a change in clinical practice from poor-quality studies that, at best, only suggest important questions to be studied.

VI. SUMMARY

KEY CONCEPTS

- Changing demography in the Unites States will change emergency medicine practice.
- Disparities in health and health care delivery continue despite efforts to improve care. Emergency physicians and their institutions will need to be part of the solution—treating preventable conditions that become crises because of reduced access to both primary care and specialists and acting as advocates for strategic system change to eliminate disparities in their institutions.
- Emergency physicians will improve the quality of care provided if they practice to meet federal standard for culturally and linguistically appropriate care, recognizing that patients with limited English proficiency have a right to medical interpretation.
- Culturally sensitive, patient-centered, and trauma-informed care will improve patient–emergency physician communications and satisfaction, decrease medical errors, and promote patient follow-through with recommendations.

Multiculturalism and Care Delivery

Thea James, Edward Bernstein, and Judith Bernstein

PERSPECTIVE

Every day, in emergency departments (EDs) throughout the United States, physicians encounter challenging cases that require an appreciation of cultural differences. Lack of understanding of the role of cultural factors can have an adverse effect on physician-patient communication and trust. Health outcomes can also be negatively affected, as demonstrated by a large body of literature on racial and ethnic disparities in types of interventions and outcomes for heart and lung disease. Race, culture, ethnicity, class, gender, economic conditions, spirituality, and sexual orientation define health and illness for patients and affect both access to health care and the quality of services received. Missing these cues may lead to medical errors.[1,2]

The American College of Emergency Physicians (ACEP) Code of Ethics commits emergency physicians to "protect the rights and best interests of the most vulnerable . . . [and] secure access to emergency and other basic health care for all."[3] This code also recognizes that "denial of emergency care or delay in providing emergency services on the basis of race, religion, ethnic background, social status, type of illness or injury, or ability to pay is unethical." Lewis Goldfrank, past president of the Society for Academic Emergency Medicine (SAEM) and a member of the Institute of Medicine, and Robert Knopp, a member of the editorial board of *Annals of Emergency Medicine,* comment in an editorial about ethnic disparities in ED analgesia prescription:

> *With the legacy of racism . . . as well as the growing body of medical evidence indicating differential care in emergency medicine and other medical specialties, we believe that the burden of responsibility has now shifted so that the medical profession must demonstrate that physicians are providing appropriate and timely care for all. . . . Our integrity as a profession and as a nation hangs in the balance.*[4]

The purpose of this chapter is to provide the knowledge base in cultural competence that is essential to meet patient needs, to improve health outcomes, to reduce racial and ethnic disparities, and to achieve professional goals.

RATIONALE FOR CULTURAL COMPETENCE

Changing Demographics: New Challenges for Emergency Physicians

We live in a global community, and both the U.S. population and the types of health problems seen by emergency physicians are constantly changing. In 2000 the U.S. Census Bureau estimated that 12% of the U.S. population was foreign born and 20% spoke a language other than English at home.[5] According to the 2010 Census, 27.6% of the U.S. population identifies as other than solely "white," and 16.3% describe themselves as Hispanic or Latino.[6] It is projected that by 2030 the proportion of Hispanics will increase from 13 to 20%, and racial and ethnic minority representation in the United States will exceed 40%.[7]

These figures do not speak to the diversity within these groups. The category Hispanic, for example, is an ethnic grouping counted in the race category of the census, but it fails to capture the significant range of diversity represented by Spanish speakers. Hispanics may share some cultural practices and speak similar versions of the Spanish language but have major differences in vocabulary and dialect, history, socioeconomic status, cultural identity, what they call themselves (Hispanic or Latino), levels of acculturation, health beliefs, habits, access to care, and health outcomes.

What do these changes in demographics mean to practicing emergency physicians? The ACEP Code of Ethics challenges us to recognize ethnic and racial differences in health care access and outcomes, to advocate for equity, and to work with other health organizations and providers to contribute to elimination of these disparities.

Racial and Ethnic Disparities in Health Care Access and Outcomes

In the past decade, both financial and nonfinancial barriers to access for racial and ethnic minority populations have been thoroughly documented. These include high rates of uninsurance, lack of prenatal care, hospitalizations for ambulatory-sensitive diagnoses (an indicator of reduced access to primary care), and concentration of minorities in areas of physician shortage.[8] In 2003 the Institute of Medicine (IOM) produced a report commissioned by the U.S. Congress in which more than 100 studies assessing the quality of care for racial and ethnic minorities living in the United States were analyzed.[9] According to the IOM report, minorities received fewer needed services and procedures than whites did, after control for insurance status, income, and other access factors. These findings applied to a wide range of health conditions, such as cancer, cardiovascular disease, human immunodeficiency virus (HIV) infection and AIDS, diabetes, and mental illness. The findings identified cultural and linguistic barriers, fragmentation of the health care system, and differences in sites of care delivery and insurance coverage as explanatory factors. The authors suggested that unconscious bias, prejudice, stereotyping, and physician uncertainty of severity may influence clinical decision-making and allocation of services and procedures. Patient preferences may account for some of the range of distribution of services, but preference alone is insufficient to explain health care disparities.

www.ketabpezeshki.com 66485457-66963820

The report concluded that "racial and ethnic disparities in health care exist, and because they are associated with worse outcomes in many cases, they are unacceptable."

The IOM report also discussed important nonfinancial barriers to access, such as the unequal distribution of physicians in areas where minority populations live. In particular, the number of racial and ethnic minorities living in medically underserved areas is three times the proportion of minorities in the general population. Poor urban communities with high African American and Hispanic representation averaged 24 physicians per 100,000 people compared with 69 physicians per 100,000 in communities with low representation. Although minority physicians are more likely to serve patients with Medicaid or no insurance, enrollment of minorities in health profession schools has been declining for African Americans, Hispanics, American Indians, and Alaskan Natives.[10] In fact, the Association of American Medical Colleges (AAMC) reported that in four states with restrictions against affirmative action, in the year following enactment, there was a 17% decline in applications and a 26% decline in matriculation to medical schools from under-represented minority groups.[11] A survey conducted in 1997 by the SAEM Task Force on Women and Minorities found that 59% of residency-affiliated sites had no minority faculty member.[12] Jordan Cohen, past-president of the AAMC, argues that "to achieve diversity in the health professions is not someone else's problem; it is a problem for the profession, for all of us who are concerned about the future access to health care and the quality of health care that we are going to be able to provide our society."[13]

The National Institutes of Health National Center on Minority Health and Health Disparities, created by Congressional Public Law 106-525 to oversee research in health care disparities, reported that improvements in health have not been universal during the past two decades: "Striking disparities in the burden of illness and death" exist for African Americans, Hispanics, Native Americans, Alaskan Natives, Asians, and Pacific Islanders. Despite a decade of attention focused on racial and ethnic health care disparities, progress in narrowing of critical gaps in life expectancy has been slow. Life expectancy for blacks as a whole is 73.2 years versus 78.3 years for the white population, a gap of 5.1 years. For black men versus white men, the gap is even larger (6.2 years). Lower life expectancy for blacks is accompanied by higher rates of cardiovascular disease, cancer, infant mortality, maternal mortality, birth defects, asthma, diabetes, stroke, intentional injury inflicted by others, sexually transmitted disease, and mental illness.[14,15] The reliability of data for Hispanics is limited by the inaccurate reporting of race and ethnicity on birth and death certificates, the healthy migrant effect, and the possibility that migrants may return to their country of origin when they become ill or disabled.

Factors Contributing to Disparities in Health Outcomes

In the past decade, reports have been regularly published in major peer-reviewed journals about disparities in the use of diagnostic tests and procedures, access to appropriate treatment modalities, and waiting times to receive care in the ED.[16,17] The Coalition to Reduce Racial and Ethnic Disparities in Cardiovascular Disease Outcomes (CREDO), for example, acknowledges racial and ethnic differences in cardiovascular comorbidities, use of evidence-based therapies, and prolonged time to reperfusion and a race-based invasive procedure gap for coronary intervention.[18]

Test and Treatment Options: Physician-Patient Communication Failure?

Studies document clearly that both Hispanics and African Americans receive fewer analgesics for extremity fractures[19-22] and for musculoskeletal pain[23] than white patients do in the ED setting, despite no evidence of difference across race and ethnicity in the ability to discriminate painful sensation.[24,25] In secondary analyses of the National Hospital Ambulatory Medical Care Survey (NHAMCS) data for 1993 to 2005, opioids were less likely to be prescribed to African Americans (23%) and Hispanics (24%) for pain relief than to whites (31%),[26,27] and these differences were greatest for patients with the most severe pain.[26] Disparities in ED pain treatment continue to persist a decade after identification of racial and ethnic differences in analgesic administration. In the most recent analysis of NHAMCS data, non-Hispanic black patients presenting with abdominal pain were 1.53 times more likely than their white counterparts to experience waits of 60 minutes or more.[28]

Evidence from other specialties corroborates that differences in provision of medically appropriate procedures and therapies are often related to race and ethnicity. In the case of preventive measures, for example, elderly African Americans and Hispanics are less likely to receive influenza and pneumococcal vaccine.[29] In the domain of surgery, the operative rate for certain lung cancers was 76.7% for whites and 64% for African Americans, and the 5-year survival was 34.1% and 26.4%, respectively.[30] The authors concluded that if blacks had undergone surgery, the 5-year survival rate would have been similar. An accompanying editorial suggested that the medical establishment take some responsibility for the racial discrimination that results in inadequate emphasis on prevention or insufficiently aggressive care for African Americans.[31]

These issues also apply to disparities between black and white populations with respect to cardiovascular disease. After adjustment for severity and coexisting conditions, African Americans are less likely than whites to undergo either angioplasty or bypass surgery, and differences are more significant for those predicted to benefit most from revascularization.[32] A multicenter ED study found racial disparities in access to cardiac catheterization for African Americans and other nonwhites with acute myocardial infarction and unstable angina. The researchers also found that African American patients were less likely to receive a timely electrocardiogram or an assay for cardiac markers,[33] and in another study, physicians were less likely to prescribe anti-ischemic medications.[34]

In recent years, racial and ethnic disparities in ED treatment decisions have also been identified for admission after a diagnosis of pancreatitis,[35] for care related to mild traumatic brain injury[36,37] and headache,[38] for rate of appendicitis rupture,[39] and for underdiagnosis of psychiatric disease.[40]

Discrimination and Health Outcomes

Deleterious health consequences that result from racial discrimination have been well documented.[41-45] In a study of the nation by state, in states where more respondents to the General Social Survey indicated that blacks lacked innate ability, there was a closely associated increase in age-adjusted black mortality that was considerably stronger than the correlation for mortality and socioeconomic status.[46] Mechanisms used to cope with the stress of racism have been shown to backfire by adding to health risks, as in the case of smoking, substance abuse, and overeating.[47,48] Racism-induced stress has been shown to be negatively associated with disease entities such as diabetes, hypertension, depression, and preterm birth.[49-53] Similar experiences have been described for homosexuals vis-à-vis homophobia.[54]

Race-Based Medical Decision-Making

Racism, sexism, and homophobia can interfere with the establishment of trust and the delivery of effective medical care if providers

www.ketabpezeshki.com 66485457-66963820

create or establish barriers on the basis of their own internal biases, prejudices, and negative reactions to racial or cultural characteristics, such as skin color or clothing styles. Patients read these reactions clearly during an encounter with a provider. A barrier is created, and the opportunity for a good medical outcome may be lost. Provider biases against people with certain stigmatized diseases, such as HIV infection and substance abuse, can also create barriers to effective health care. When primary care physicians viewed scripted video interviews with hypothetical patients with chest pain who had similar symptoms, risk factors, vital signs, and thallium stress test and electrocardiographic findings, they were less likely to refer African American women for cardiac catheterization than men and whites, even though the scripts varied only by race and gender.[55] Disparities profiling can result in both underdiagnosis and overdiagnosis and thus contribute to medical error.[56,57]

Failure of Trust

Patients from minority communities have reason to be skeptical about the validity of medical research and the appropriateness of medical recommendations. Participants in the Tuskegee study, for example, were not notified when effective treatment of syphilis became available because researchers wished to investigate the natural course of the disease.[58] Middle-class African American patients often rate their physician interactions as more participatory when their physician is of the same race.[59,60] Yet this option for physician-patient congruence is rarely available to minority patients because only 4% of physicians are black, whereas 12% of the population is black.[9]

In the Agency for Healthcare Research and Quality *National Healthcare Disparities Report,* blacks and Hispanics were found to be more critical of the patient-provider relationship than were whites. A higher percentage of adult blacks and Hispanics rated their health care at less than 6 on a scale of 1 to 10 in the past year and believed that they would have received better care if they were of a different race or ethnicity. The report provided evidence confirming perceptions of a lower quality of medical care. For example, when black and Hispanic elders were hospitalized for pneumonia, they were less likely than comparable whites to have blood culture samples drawn and antibiotics administered in accordance with current recommendations. Hispanics with myocardial infarction were less likely to receive aspirin or a beta-blocker on admission and discharge. In comparison with white dialysis patients, fewer blacks and Hispanics in need of a kidney were registered on waiting lists for a transplant or had received a transplant within 3 years.[61]

Language and Effective Medical Care

According to the 2000 U.S. Census, 47 million Americans (18%) speak a language other than English at home, 21.3 million speak English less than very well, and 10.7 million speak English not at all or not well.[62] Patients with limited English proficiency are more likely to defer needed services, to leave against medical advice, to miss appointments, to fail to adhere to treatment regimens, to lack a regular provider, and to report poorer health status.

Transcribed audiotapes of medical encounters in a pediatric ED setting were studied to ascertain differences in communication error rates for patients who were aided by professional hospital interpreters compared with those who had an ad hoc interpreter (e.g., family, friend, or nonprofessional hospital worker) and those who had no interpreter available. The investigators found that communication errors occurred equally among the ad hoc and the no interpreter groups. These errors included left out words (52%), incorrect words (16%), substituted words (13%), interjected personal views (10%), and added words (8%). The errors of ad hoc interpreters were more likely to result in clinically significant medical errors, such as omitting drug allergies and giving inaccurate instructions on dosing and route of administration.[63] The use of untrained nonprofessional employees as interpreters resulted in serious translation errors, including omissions, additions, and substitutions for what the patient is trying to say, and the use of relatives, particularly children, may violate privacy and disrupt family norms of authority.[64-67]

A cross-sectional survey at a public hospital ED suggests that there is a patient-perceived need for interpreter services, and the highest patient satisfaction ratings are obtained when patients can communicate directly with their physicians.[68] Satisfaction ratings for patients using ad hoc interpreters are lower, and rates are lowest when an interpreter should have been used but was unavailable. In one retrospective study of Spanish-, Haitian Creole–, and Portuguese Creole–speaking patients presenting to the ED with chest pain, headache, and abdominal pain, the investigators found that the use of trained interpreters was associated with increased intensity of ED services, reduced ED return rate, increased clinic use, and lower charges during the next 30 days, without any simultaneous increase in length of stay or cost of visit.[69]

A statewide ED patient satisfaction survey in Massachusetts indicated that non-English speakers were less satisfied with their care, were less willing to return for care, and reported more problems with emergency care.[70] The authors stated that interpreter service is likely to improve the satisfaction of this group.

Evolution of New Standards for Health Care

In response to the identification of unacceptable differences in both health care provision and health care outcomes, state Medicaid regulations and Health Plan Employer Data and Information Set (HEDIS) criteria now reflect the need to establish quality performance measures to ensure access to appropriate services for culturally diverse populations.[71] A new standard of care[72] has been established that requires institutions and practitioners to provide for medical needs in a patient's primary language and in a manner compatible with the patient's health beliefs and practices. Health care institutions and providers are asked to collect data stratified by race, ethnicity, and language and to institute quality improvement efforts when cross-cultural differences in outcomes of care, process indicators, or patient satisfaction are detected. They are asked to develop culturally competent systems of care based on an assessment of the organization's mission, goals, policies, practices and services, staff training needs, and current diversity of the staff.

After the assessment process, health care organizations must identify opportunities to improve the cultural competence of the organization and its delivery of health care services to a diverse population. At the top of the list is the improvement of interpreter services. Hospitals are asked to establish minimum performance standards for interpreters that include training in culturally specific medical language and code of ethics. These requirements have been codified as a set of standards for culturally and linguistically appropriate services (CLAS standards) by the Office of Minority Health and the Agency for Healthcare Research and Quality and published in the Federal Register (December 15, 2000).[72] In spring 2000, the Massachusetts legislature took a positive step in the direction of compliance with these standards by passing a law requiring all EDs to provide interpreter service and authorizing the state to provide Medicaid reimbursement for interpreter services.

www.ketabpezeshki.com 66485457-66963820

Culturally Competent Approach to Language Barriers

In 1996 the SAEM Task Force on Physician-Patient Communication identified lack of a common language as the most common barrier to communication in the ED. Professional medical interpreters were recommended for the following reasons: confidentiality, medical knowledge and a common vocabulary with the provider, and fluency.[73] Two case reports illustrate this point.[74]

A 50-year-old Mexican American man who spoke only Spanish was seen in the ED because of "chest pain." Because no translator was available, an electrocardiogram and chest radiograph were ordered. The electrocardiogram was normal; the chest radiograph showed a widened mediastinum suggestive of a dissecting aortic aneurysm. An aortogram was subsequently performed, which demonstrated a normal aorta. At some point, a Spanish-speaking physician was able to elicit a 1-year history of difficulty in swallowing and regurgitation of food. A barium swallow was performed, which revealed achalasia.

A 22-year-old Vietnamese man arrived in the ED unresponsive and comatose with small, reactive pupils. Naloxone hydrochloride and 50% dextrose in water were administered without response. The medical history was obtained from a family member who spoke limited English. It consisted of brief answers to specific questions and was not helpful diagnostically. A lumbar puncture and examination of the cerebrospinal fluid ruled out meningitis. A clerk later recalled that a child with the same last name was admitted the previous day for headache, nausea, and vomiting caused by carbon monoxide poisoning. In retrospect, it was clear that the history obtained from a family member who was under stress and giving vague answers to pointed questions was inadequate. The authors concluded that "a trained bicultural translator can effectively elicit the history as conceptualized by the patient or family and translate it both linguistically and in the format of Western medicine."

The preceding example also illustrates that bilingualism is necessary but not sufficient. There are nuances and sociocultural assumptions in both languages and nonverbal cues that must be communicated along with words for effective diagnosis, treatment, and disposition. The medical interview is the heart of the medical encounter between physician and patient, yet in an interpreted interaction, neither patient nor physician is in a position to judge the accuracy or completeness of a lay interpreter's translation. Clearly, omissions, additions, opinions, guesses, and distortions can lead to serious mistakes and unnecessary diagnostic procedures.

Standards and certification for medical interpreters are needed to ensure consistency and quality. The Massachusetts Medical Interpreter Association recommends that standards cover interpretation, the cultural interface, and ethical behavior. Because the meaning inherent in the message is rooted in culturally specific beliefs, values, assumptions, customs, and norms, and language is itself an expression of culture, it may be necessary for a medical interpreter to go beyond a literal interpretation to explain unstated assumptions and to find new ways of communicating untranslatable words or concepts. In addition to maintaining confidentiality, the medical interpreter has an ethical burden to uphold the trust of both parties and to assure them that the considerable power associated with the interpreter's role will not be abused and that information will be faithfully conveyed without interjection of the subjective opinions and thoughts of the interpreter. Even with such qualified interpreters, the emergency physician still needs to monitor the flow of the interview and, from time to time, clarify meaning and ensure understanding. This can be done by having the interpreter repeat what he or she thought the patient meant and asking the patient to repeat what the interpreter said. It is important to observe the interaction for phrase length as an indication of material not translated or added by the translator.

Multiculturalism, Cultural Competence, and Health Disparities: Progress to Date

The 2003 IOM report revealed disparities in health care in America based along lines of race and ethnicity.[9] The recommendations to reduce these health care disparities included "integration of cross-cultural education into the training of all current and future health professionals." Progress has been slow in actually reducing health disparities,[75] and gaps in economic resources between white and minority populations have actually widened,[76] increasing the barriers impeding access to timely, effective care.

Forward movement has primarily occurred in the form of establishment of guidelines and standards at local, state, federal, public, and private levels. The Joint Commission's *A Roadmap for Hospitals* encourages hospitals to incorporate concepts from cultural competence, patient-centered care, and communication into their organizations. These efforts include increasing awareness of health disparities, efforts to improve collection of race and ethnicity data across systems of care, quality improvement, community outreach, increasing workforce diversity, patient education, provider education, and increased availability of interpretation services. A policy system of checks and balancing now exists, with national performance monitoring affecting accreditation of health care organizations.

In 2011, patient-centered communication standards were included in the Joint Commission's *Comprehensive Accreditation Manual for Hospitals*. In year one, hospitals will be monitored for compliance of standards, without any effect on accreditation, but in 2012, compliance with these standards will be taken into account in the accreditation process.

In another example of guideline development, the National Committee for Quality Assurance developed and released rigorous standards for monitoring and evaluation of multicultural health care in 2010. Multicultural health care distinction is conferred on health care organizations that conform to acceptable practices in race/ethnicity and language data collection, access and availability of language services, practitioner network cultural responsiveness, programs for culturally and linguistically appropriate services, and overall efforts to reduce health care disparities. In a similar effort, the National Quality Forum released a report in 2011 on quality measures to assess cultural competence. In education, the Liaison Committee on Medical School Education now includes cultural competency in its accreditation standards. Medical students should learn to recognize and appropriately address gender and cultural biases in themselves and others and in the process of health care delivery.

Disparities awareness has also been included in health care reform. The Patient Protection and Affordable Care Act (Health Care Reform Act) signed into law in March 2010 requires data collection on race, ethnicity, primary language, disability status, and gender. These data can identify areas of concern and provide opportunities for intervention. This law follows recommendations from the IOM report of 2003 and raises awareness of culture and disparities. In addition to national activities, many states have taken action. For example, the New Jersey State Board of Medical Examiners requires that physicians licensed in New Jersey complete six credits in cultural competency (Rule N.J.A.C. 13:35-6.25).

Using Cultural Competence to Cross the Barrier of Different Beliefs, Values, and Life Experiences

Both physicians and patients have a culture that they bring into the examining room. Differences between their cultures have an

www.ketabpezeshki.com 66485457-66963820

impact on the physician-patient encounter. Awareness of one's own values and those of others can enhance both satisfaction and health outcomes. The SAEM task force report cautioned, however, that it is dangerous to hold strong preexisting assumptions about any cultural group because variations within cultures often exceed variations between them. A patient who is thoroughly acculturated into American society may be offended by a health care provider's attribution of traditional beliefs. Even in the context of a busy ED encounter, it is necessary and feasible to get to know the individual patient sufficiently to make a rough assessment about level of acculturation or at least to ask rather than to assume.

In some cultures, the diagnosis of specific diseases can be particularly problematic. For example, in African American and Puerto Rican communities, cancer is often perceived as a fatal disease. Patients may therefore avoid initial evaluation or choose no treatment when they are diagnosed, even when the cancer is identified at an early stage and the prognosis is good. A health care provider who understands these health beliefs and concerns can work collaboratively with patients to provide health information in a format that the patient can accept.

Alternative healing systems have strong cultural roots. In 1997 the U.S. population made an estimated 629 million visits to providers of alternative health care—approximately 243 million more visits than to conventional health care providers and an increase of 47% since 1990. An estimated 44% used at least one complementary alternative therapy in 1997.[77]

Folk medicine is too diverse for providers to know all possible practices, but emergency physicians need to know some of the more common therapies and ask their patients about them. For example, more than a few emergency physicians have called social workers to investigate children with apparent bruises caused by coining, which involves vigorous rubbing of the skin with coins and warm oil (tiger balm) to release the "bad wind" (reduce fever). These parents, who have attempted to help their children by using health care practices that are widely accepted in their communities of origin, feel accused, and the trust between the physician and the family may be irrevocably lost. Similarly, herbal remedies can be effective or at least harmless, but they can occasionally be toxic, as in the case of clay ingestion by pregnant women, marijuana tea to treat asthma, and powders containing high concentrations of lead oxide to treat *empacho,* a condition in which it is believed that a substance (usually food or saliva) gets "stuck" to the walls of the stomach or intestines, causing an obstruction. Specific uses of folk medicine need to be elicited respectfully in a careful history and evaluated. Recommendations can then be presented nonjudgmentally, and alternative folk remedies that are benign can be prescribed along with needed allopathic medications.

The practitioner and the patient will inevitably bring different beliefs and values to the medical encounter; the key to cultural competence is respectful negotiation of these differences without imposing the power of the physician's expertise, thus protecting the patient's autonomy. If patients are satisfied, they will carry out follow-up recommendations and return to the ED in the future when they need emergency care.

In a review of Hispanic cultural practices, Flores suggested a five-step approach for the pediatric ED that is applicable to all emergency medicine: The physician should (1) explain that he or she is aware that a given folk illness exists; (2) ask whether the parent or patient has ever heard of it; (3) ask whether the patient has the folk illness now; (4) ask what treatment the patient is receiving for the condition; and (5) suggest alternatives to harmful folk remedies, accommodating wherever possible (nonjudgmentally) to folk illness beliefs and practices and integrating the use of harmless folk remedies into the treatment plan when the patient so desires.[78]

Interpreting the Culture of Medicine to Patients from Diverse Backgrounds

There are inherent conflicts between the culture of medical care, particularly ED culture, and the cultures of many patients. Physicians are expert in diagnosis and treatment of *diseases,* which represent abnormal structures or functions of the human body (the pathophysiology of disease states). On the other hand, patients experience *illness,* a subjective, feeling state that is interpreted through the lens of culture and has a personal and social meaning. The patient is an expert in his or her own illness and its effects on daily living, whereas a physician is expert in the effects of diseases on organ systems. Both ways of looking at the world have validity, but they are radically different.[79] Unfortunately, the culture of medicine tends to recognize only its own interpretation and perspective. A culturally competent approach recognizes both and works to integrate the best of both worlds.

A patient may have very high blood pressure, HIV infection, or early cervical cancer and not experience symptoms. If patients do not feel sick and experience no alteration in functioning, they may not accept a physician's diagnosis. There may be conflict between the patient's perception of causality and the physician's, as in the case of the differences between the medical diagnosis of hypertension and the commonly accepted view of hypertension as "high blood" in the African American community.[80]

On the other hand, a patient may feel sick—be ill, weak, and dizzy, with extreme fatigue or abdominal pain—yet the physician is unable to diagnose a disease despite a thorough history, physical examination, testing, and appropriate consultation. For example, *susto,* an illness recognized by Mexican Americans, causes listlessness, insomnia, depression, and anorexia and is believed to be caused by exposure to a frightening experience. Treatment requires the patient to speak openly about the events that led to the susto, followed by bed rest and a ritual that includes prayers, incantations, and *barridas* (sweeping of the body with an egg, a candle, or herbal teas).[81]

To be most effective, physicians need to investigate how patients view the causality of their illnesses and how they experience them to negotiate a therapeutic intervention. Exploration might take the form of comments and questions, such as, "Help me to see through your eyes how you understand this problem. Have you or someone you know experienced it before?" The role of the physician is to accept the patient's experience as uniquely his or hers or, when possible, to reframe it in terms of medical knowledge. Then both physician and patient will be satisfied with the outcome of the encounter.

Trauma-Informed Care

Because urban, black youth and other minorities are overrepresented among victims of violence, racial and ethnic stereotyping can play a direct role in trauma care. In 2007, more than 668,000 youth between the ages of 10 and 24 years were treated in U.S. EDs for violent injuries.[82] Assumptions of responsibility and guilt by ED clinicians can produce a hostile environment for patients who have been shot or stabbed. Language that assumes blame ("What did you do?" instead of "What happened to you?") indicates a lack of understanding of the complexity of trauma, its neighborhood context, and the psychological impact of adverse childhood events, which are often at the epicenter of the cycle of violence.[83,84] For example, the emotional response to trauma of a victim of violent injury can be misinterpreted as negative behavior. A victim might be seen as ill willed versus in need of care and healing. Providers and health care staff witnessing the responses of these violently injured youth have an opportunity either to mitigate the trauma or inadvertently to enhance it through retraumatization.

www.ketabpezeshki.com 66485457-66963820

A new construct, trauma-informed care,[85-87] is an alternative perspective that can enhance opportunities for productive encounters, self-reflection, and positive medical outcomes during a vulnerable time for an injured young person. The basic set of principles includes creation of a safe physical and emotional environment that is sensitive to the needs of victims of violence, promotes recovery, and prevents revictimization. Symptoms are seen not as pathologic changes but primarily as attempts to cope and to survive. Trauma-informed care can result in an injured youth's choosing "change" versus unsafe behavior that could result in injury, reinjury, or incarceration. One of the policies of the 2011 ACEP Revised Code of Ethics reads that emergency physicians have a "duty to promote the public health." The code states, "Emergency physicians have first-hand knowledge of the grave harms caused by firearms, motor vehicles, alcohol, and other causes of preventable illness and injury." The code suggests that emergency physicians have a responsibility to act: "Inspired by this knowledge, emergency physicians should participate in efforts to educate others."[88]

Role Expectations in Western Medicine: Opportunity for Misunderstanding

The culture of medicine, especially in emergency medicine, may have its own set of patient expectations, rules and regulations, language, and dress distinctions that reflect a hierarchy of authority, a characterization of patients as good or bad, and different sets of behaviors toward patients, depending on the category to which they have been assigned. People from different cultures may find it impossible not to violate some of the unwritten negative and stereotypical rules and regulations of the ED. Every medical encounter is potentially a cross-cultural experience, and negotiation of the divide is a challenge for both patients and providers. Cultural competence involves a reframing of many of these unstated rules because they prevent us from looking beneath the surface and addressing real problems. When a patient comes in with vague complaints, there may be a social stressor that has tipped the balance of mental health. There may be circumstances that the patient does not feel comfortable sharing with the provider because of cultural, racial, or language barriers, or there may have been an overload of negative stimuli related to racial and ethnic discrimination—a crisis for the person and the body this person inhabits.[89,90] People from minority cultures experience stressful events daily that the white providers, secure in their socioeconomic status and membership in the dominant majority, can only imagine. There is mounting evidence that these types of negative encounters engender clinical depression and anxiety and contribute to hypertension and other medical sequelae. If patients self-define themselves as having an emergency condition by showing up at the ED, the problems that cause those individuals to come deserve our respect.

A study of racial and ethnic patterns of ED use found that four times as many African Americans and Hispanics as whites report the ED as a source of care.[91] Patients who "overuse or abuse" the ED are seen as "bad patients," but the reasons given in this study for patients' use of the ED are entirely rational: the ED does not require an appointment to receive care, provides sophisticated medical technology, operates 24 hours a day, provides services that are often covered by health insurance plans whereas other options often are not, has a tradition of free care, and is often located close to inner-city neighborhoods, whereas many primary care providers have abandoned the city-center environs for the suburbs. These reasons may explain, at least in part, why U.S. EDs had more than 120 million visits in 2010.

To practice good medicine in this health care and social environment, emergency physicians should critically question and reframe the moralistic good patient/bad patient paradigm. We, like our patients, are at the whim of forces beyond our control, and both patients and practitioners will experience higher levels of satisfaction if these issues are addressed directly. Patients must take responsibility for their own behaviors whenever possible, but physicians can and should work with health care institutions to adopt policies that improve access to culturally competent health care. These actions can help create a safe environment for both practitioners and patients.

CULTURAL COMPETENCE AND PATIENT-CENTERED CARE: NEW MODELS

Models for cultural competence and for patient-centered care have evolved separately yet in tandem.[92] The goal of both is to improve the quality of the health care experience in a multicultural world, and there are areas of overlap. Whereas cultural competence evolved from the perspective of recognizing and respecting individual difference and the impact of individual interpretation on health, illness, and health care delivery, patient centeredness addresses *systems* of health care delivery, improving access, and meeting patients where they are to maximize opportunities for successful health care.[93] Ideal health care systems should be designed to incorporate principles of both cultural competence and patient centeredness. A health care system built on patient-centered principles represents the heart of cultural competence (seeing the problem and the solution from the point of view of the patient).

EDUCATION

Education about the impact of culture on health care encounters is a key component for development of culturally appropriate health care and is a requirement for organizational accreditation. Students and residents in training consistently express greater levels of comfort in multicultural environments when they have had preparatory training. Training also helps students and residents understand that their own culture also affects clinical encounters and is equally participatory.[94-98] Continued re-education raises awareness and more permanently imprints consciousness, establishing a conceptual norm for those interacting and working in multicultural environments. Linkage of cultural competence with ethical constructs of equal distribution of resources and social constructs of justice gives meaning to principles and context beyond memorization of appropriate responses to model situations.[99]

Medical schools are now required to include cultural competency training in their curriculum for accreditation. Faculty and students should demonstrate an understanding of the manner in which people of diverse cultures and belief systems perceive health and illness and respond to various symptoms, diseases, and treatments. Medical students should learn to recognize and appropriately address gender and cultural biases in themselves and others and in the process of health care delivery.

RECOMMENDATIONS

Diversity among the ED patient population poses a challenge to emergency physicians. Recognition of cultural differences, knowledge about diverse cultures, awareness of the health impact of cultural beliefs and practices, and sensitivity to patients' needs can reduce access barriers and improve clinical outcomes and hospital-community relationships while reducing the number of repeated visits and the cost of health care. Diversity education also creates

www.ketabpezeshki.com 66485457-66963820

a rich environment for conceptualizing and researching health problems.[100,101]

There are many opportunities for EDs and their institutions to improve their care of multicultural communities. These include plans to address problems related to the following: a lack of protocols for patient care; a lack of resources for translation and cross-cultural interpretation; an incorrect perception that attention to cultural competence adversely affects flow and efficiency; a lack of cross-cultural teaching guidelines and standards in medical education; the inadequate recruitment and retention of minority residents, faculty, and practitioners; and a lack of pathways for communication and collaborative work with communities.

Concrete recommendations, based on the CLAS standards, have been proposed for pediatric emergency settings and can be applied universally. Institutions should use trained medical interpreters and a diverse workforce. Pharmacies should label prescriptions and provide medical instructions in the patient's primary language. Administrators should post multilingual signs and ensure that handouts and forms are translated. Quality improvement programs should collect and analyze data and provide information to monitor outcomes based on race and ethnicity. A diverse group of patients should be enrolled in research studies to improve outcomes.[102]

Recommendations from the IOM report for a series of additional legal, regulatory, and policy measures were highlighted in an *Academic Emergency Medicine* editorial and include the following:

Patients in public managed care organizations should have the same patient bill of rights as patients in private health maintenance organizations.

The number of health care providers who are members of racial and ethnic minority groups should be increased.

Resources should be adequate to enforce penalties for civil rights violations.

Incentives to promote disparities should be stringently limited.

Health care professionals should have opportunities for cross-cultural education.

Patient participation in decision-making should be enhanced through education.

Community health care workers and advocates should assist patients to negotiate the health care system successfully.

The diversity of faculty and residents must be improved.

A cross-cultural curriculum should be developed for residency training and continuing education.

Physicians should educate themselves and the general public about the need to eliminate racial and ethnic disparities in health care.[103]

SUMMARY

Changing demographic landscapes in EDs have set the stage for multiculturally appropriate care. The process of change for development of culturally competent medical systems has been slow, but progress is occurring. Evolution of culturally appropriate environments for patients and their families has begun on all levels, and with the development of new standards and performance-monitoring systems, assurance of established culturally competent systems will be an expectation. These expectations are important and tightly linked to both safety and quality. The linkage of cultural competence to social justice broadens the depth of comprehension for the learner and provides opportunities for enhanced engagement with consumers and greater quality of care.

There is greater awareness of and movement toward a health care system that is rooted in cultural competence and patient centeredness. It is imperative that EDs invest in development of their health care systems and educate all staff. ED patients are most often unknown to providers, who have one window of opportunity to obtain accurate information and to make a correct decision. Decisions are heavily based on one's ability to successfully engage with patients and their families, engendering comfort, trust, and respect. Continued education at all levels is key and should include everyone working in health care, especially those who engage with consumers. Multiculturalism education should be integrated into medical school curricula, physician training programs, allied health programs, new employee orientation, and regularly for staff in-service programs.

The process of creating a successful plan to move cultural competency from a theoretic model to one of action and implementation is outlined in six principles that incorporate key points recommended by the IOM report of 2003 for systems aligned with new cultural competence standards and expectations:

- community representation and feedback at all stages of implementation;
- cultural competency integrated into all systems of the health care organization, particularly quality improvement efforts;
- ensuring that changes made are manageable, measurable, and sustainable;
- making the business case for implementation of cultural competency policies;
- commitment from leadership; and
- staff training on an ongoing basis.

Essential cultural competence tools for providers include recognition of cultural differences, respect for individual opinions and perspectives about health and illness, and, most important, ability and willingness to negotiate differences to offer the best opportunity for good health care outcomes. Culturally appropriate health care systems should be incorporated into EDs, which serve as the gateway to our health care institutions. Basic skills proposed in an intercultural curriculum developed by Goldstein and associates for internal medicine residents can apply equally to emergency physicians (Box 1).[104] Policies that will promote cultural competence, increase patient satisfaction, and improve health outcomes include those listed in Box 2.

Box 1 Basic Skills in an Intercultural Curriculum

Communicate an interest in and respect for the patient's culture.

Tactfully and respectfully ask for general cultural information (e.g., herbal remedies, acupuncture, coining, moxibustion, or other cures attempted).

Elicit the patient's understanding of and beliefs about illness or health problems.

Request information regarding folk medicine beliefs—for instance, "mal ojo" (the evil eye or evil spirit) among Mexican Americans, voodoo among Haitians, yin and yang among Chinese patients, "rootwork" among African Americans, and "spiritism" (the ability of spirits to make people sick or cure them) among Puerto Ricans.

Interpret verbal and nonverbal behaviors in a culturally relevant manner.

Negotiate a culturally appropriate health care plan with the patient and his or her family as partners.

Demonstrate an ability to work as a team with a medical interpreter in the bilingual medical encounter.

From Goldstein E, et al: Intercultural medicine. In Jensen N, Van Kirk J, eds: A Curriculum for Internal Medicine Residency. Philadelphia, American College of Physicians, 1995.

Box 2 Policies for Institutional Improvement

Educate emergency department personnel about the circumstances of patients' lives and the interesting cultures that have evolved to deal with these circumstances by use of a variety of formats:
- A series of hospital in-services to provide information about each specific patient group that uses the institution
- Small focus groups with patients to improve our understanding of our patients' needs and to begin the process of freeing providers from racial and ethnic stereotypes that create barriers to good medical care
- Training with use of videotapes and role-playing exercises to enhance movement along the cultural competence continuum

Meet with community organizations to build trust and to create partnerships for preventive education.

Hire employees who reflect the culture, ethnicity, and socioeconomic background of emergency department patients to improve the quality of services.

Provide interpreter services, visual aids, and other educational materials in a variety of languages, and provide multilingual health education classes.

Participate as an institution in community health fairs.

Educate emergency department and all staff who interface with victims of violence about trauma-informed care.
- Develop in-service for new hires; incorporate in human resources department hospital orientation
- Periodic updates: hospital-wide series on trauma-informed care

Educate medical students, physicians in training, and all providers about patient centeredness, cultural competence, and the differences and overlap.

KEY CONCEPTS

- Changing demography in the Unites States will change emergency medicine practice.
- Disparities in health and health care delivery continue despite efforts to improve care. Emergency physicians and their institutions will need to be part of the solution—treating preventable conditions that become crises because of reduced access to both primary care and specialists and acting as advocates for strategic system change to eliminate disparities in their institutions.
- Emergency physicians will improve the quality of care provided if they practice to meet federal standard for culturally and linguistically appropriate care, recognizing that patients with limited English proficiency have a right to medical interpretation.
- Culturally sensitive, patient-centered, and trauma-informed care will improve patient–emergency physician communications and satisfaction, decrease medical errors, and promote patient follow-through with recommendations.

Bioethics

Kenneth V. Iserson and Carlton E. Heine

PERSPECTIVE

The medical care we provide today bears little resemblance to what was available when the first edition of this book was published. What has not advanced as far or fast is our system for deciding, in a moral and fair way, what treatments to provide. Scientific development has outpaced our social and ethical framework and often leaves physicians struggling with moral dilemmas about the appropriateness of tests and procedures. This chapter is an introduction to our current tools for helping emergency physicians (EPs) approach ethical, rather than medical, dilemmas.

Definitions

Bioethics, a subset of ethics, is the application of values and moral rules to find reasoned and defensible solutions to actual or anticipated moral dilemmas facing clinicians. The moral precepts that underpin ethical decisions are derived from a variety of sources, including individual, cultural, and community value systems. Unlike the law, which is relatively rigid and, particularly in the case of scientific and medical issues, can lag years or even decades behind modern developments, bioethical constructs allow a greater flexibility in decision-making. EPs are often called on to identify a patient's personal, cultural, religious, or community values and to balance these values with their own personal and professional ethos. A working knowledge of bioethics greatly enhances the EP's ability to make reasonable, ethical decisions in the limited time frame common to the practice of emergency medicine (EM).[1]

In contrast to professional etiquette, which relates to standards governing the relationships and interactions between providers, bioethics deals with relationships between providers and patients, providers and society, and society and patients. Issues within the realm of professional etiquette include billing, referrals, advertising, competition, conflicts of interest, professional courtesy, and employment and supervision of auxiliary personnel. These are quite different from bioethics' concerns of basic moral values and patient-centered issues. Although the two areas occasionally overlap, each relies on different standards, values, and problem-solving methods.

Ethics and Emergency Medicine

In EM, the focus is inevitably on the inherent "medical" nature of each case; therefore, it should come as no surprise that ethical dilemmas often go unrecognized. EPs may also misperceive ethics as embodying the dictates of secular or religious law or as a discipline that describes irresolvable issues.[1]

This chapter addresses a number of ethical issues in EM. What follows are brief discussions of the relation of law to bioethics; bioethical values and principles; moral imperatives in EM; ethical oaths and codes; applying bioethics to clinical situations; bioethical dilemmas in EM; a rapid decision-making model for ethical dilemmas; advance directives; the relationship between consent, decision-making capacity, and surrogate decision makers; ethical issues in resuscitation; and ethical issues in public policy.

BIOETHICS AND THE LAW

Basic Considerations

EPs often look to the law for answers to thorny dilemmas. Yet, except in the rare cases of "black-letter law," wherein specific actions are delineated, these issues are best served by turning to bioethical reasoning and using bioethics consultations. It is said that good ethics makes good law but that good law does not necessarily make good ethics. Societal values are incorporated both within the law and within ethical principles and decisions. Laws are rules of conduct established by legislatures, administrative agencies, courts, or other governing bodies. They often vary from locale to locale and are enforceable only in the jurisdiction where they prevail. By contrast, ethics is more universal within a culture, incorporating the broad values and beliefs of correct conduct. The primary differences between law and bioethics are shown in Table 1.

Modern bioethics developed because the law often has remained silent or inconsistent on matters vital to the biomedical community. The rapid increase in biotechnology, the failure of both the legal system and legislatures to deal with new and pressing issues, and the increasing liability crisis drove the medical community to seek answers to the difficult questions that practitioners have to work through on a daily basis.

Bioethical principles are not static and may evolve as societies change. The same evolution occurs within the law. For example, elective abortion, once illegal in most U.S. jurisdictions, is now legal in most circumstances and jurisdictions. Likewise, not all basic ethical principles have universal support, just as the values implicit in many legal changes have divided U.S. society.

Rights and Duties

Without a duty to act, there can be no rights. Both a moral and a logical connection exists between the rights and the duties of individuals; one cannot exist in the absence of the other. In general, a duty is an action required by the rights of others, the law, a higher authority, or one's conscience.[2] This obligation to act can be based

Box 1 Commonly Accepted Moral Rules

Moral rules govern actions on the basis of ethics and codes of conduct. These can justifiably be enforced and their violation punished. Although none of these rules is absolute, they all require one not to cause evil. Somewhat paradoxically, however, they may not require either preventing evil or doing good.

1. Do not kill.
2. Do not cause pain.
3. Do not disable.
4. Do not deprive of freedom.
5. Do not deprive of pleasure.
6. Do not deceive.
7. Keep your promise.
8. Do not cheat.
9. Obey the law.
10. Do your duty.

Modified from Gert B: Morality: A New Justification of the Moral Rules. Oxford, Oxford University Press, 1988.

on an individual's personal values, professional position, or other commitments.[3] For the physician, this duty to act is a role responsibility, at least specifically as a physician and possibly at all times. The role-duty link occurs "whenever a person occupies a distinctive place or office in a social organization, to which specific duties are attached to provide for the welfare of others or to advance in some specific way the aims or purposes of the organization."[4] In this circumstance, performance is predicated not on a guarantee of compensation but rather on a concern for another person's welfare.[5] The EP has not only such a moral duty but, because of the Emergency Medical Transportation and Active Labor Act (EMTALA), also a legal duty.

Significant overlap can exist between legal and ethical decisionmaking. Frequently, there is concurrence on basic issues. On occasion, clarity within the law can lead to clearer thinking in bioethics, and vice versa. Both law and bioethics, for example, use the term *rights,* as in "patients' rights" and "the right to die." This term, often used to advance an ethical argument about medical care, frequently is misunderstood or applied erroneously. A legal right is a demand that a person can make on another person, embodied in *in personam* rights, or against the state for recognition and enforcement of this demand. Most rights involved in bioethical discussions are *in rem* rights. These most often are negative rights because they entail someone else's duty to refrain from doing something. A common source of ethical conflict is between "active rights," the right to act or not act as one chooses, and "passive rights," the right to not be acted on by others in certain ways.[2]

VALUES

Values are the standards by which human behavior is judged. Values are learned, usually at an early age, through indoctrination into the birth culture, from observing behavior, and through secular (including professional) and religious education. Although many of these learned values overlap, each source often claims moral superiority over the others, whether the values are generic and cultural, legal norms, religious and philosophical traditions, or professional principles.[6,7] Societal institutions incorporate and promulgate values, often attempting to solidify old values even in a changing society. In a pluralistic society, clinicians treat people with multiple and differing value systems, so they must be sensitive to alternative beliefs and traditions.

This section discusses the role of religious, patient, institutional, and professional values, including professional oaths and codes specific to EM.

Religious Values

Organized religions see themselves as keepers of society's values. Even though various religions may appear dissimilar, most hold the golden rule, "Do unto others as you would have them do unto you," as a basic tenet. Other moral rules that are common to most religions are listed in Box 1. Problems surface in trying to apply religion-based rules to specific bioethical situations. For example, although "Do not kill" generally is accepted, the activities that constitute killing, active or passive euthanasia, or merely reasonable medical care vary with the interpretation of the world's religions as they do with the interpretations of various philosophers.[8-10] As members of a democracy with significant populations practicing a number of religions, EPs should behave in a manner consistent with each patient's values. The most basic underlying question is What is the patient's desired outcome for medical care?

Not only religious but also family, cultural, and other values contribute to patients' medical care decisions. Without asking, it is impossible to know what decision a specific person would make. An important point is that religion influences modern secular bioethics, which uses many religion-originated decision-making methods, arguments, and ideals. In addition, clinicians' personal spirituality may allow them to relate better to patients and families in crisis.[9]

Good versus Evil

The terms *good* and *evil* can be used to illustrate a stark dichotomy in ethical thought and values. The following is a current set of definitions that may help the physician find solutions to ethical problems. *Good* can be defined as what no rational person will avoid without a reason. Examples are freedom, pleasure, health, wealth, and knowledge. *Evil* can be defined as what all rational persons desire to avoid for themselves and for others they care about. Examples are untimely death, pain, disability, and loss of freedom or pleasure.[11] Rational persons with deeply held religious beliefs may, for example, refuse a blood transfusion, choosing a likelihood of death over the permanent pain and anguish they believe would ensue if they should violate their religious injunction. Conflicts that can be described as being between good and evil are not ethical dilemmas but rather moral temptations. Ethical

www.ketabpezeshki.com 66485457-66963820

dilemmas arise from conflicts between multiple good or multiple bad options.

Patient Values and Ethical Decisions

A key to making bedside ethical decisions is knowing the patient's values. Many people cannot answer the question, What are your values? However, physicians can get an operational answer by asking patients what they see as their goal of medical therapy and why they want specific interventions. The responses represent concrete expressions of patient values. In patients who are too young or are deemed incompetent to express their values, it may be necessary for physicians either to make general assumptions about what a normal person would want in a specific situation or to rely on surrogate decision-making. But with patients who are able to reason and communicate, care should be taken to discover what they hold as their own, uncoerced values.

Although each individual is entitled and perhaps even required to have a personal system of values, certain values have become generally accepted by the medical community, the courts, legislatures, and society at large. Autonomy and individual dignity, for example, are two such values; they have been considered fundamental and often are given over-riding importance. Although some groups disagree about each of these values, this dissension has not affected their application to medical care.

FUNDAMENTAL BIOETHICAL PRINCIPLES

Nonmaleficence and Autonomy

The basic tenet all medical students are taught is nonmaleficence: "First, do no harm." This credo, often stated in the Latin, *primum non nocere,* derives from the recognition that physicians can harm as well as help. With the physician's fallibility recognized, patient autonomy is and has been for several decades the over-riding professional and societal bioethical value. Autonomy recognizes an adult person's right to accept or to reject recommendations for medical care, even to the extent of refusing all care, if that person has appropriate decision-making capacity. It is the counterweight to the medical profession's long-practiced paternalism (or parentalism), wherein the practitioner determines what is "good" for the patient, regardless of whether the patient agrees. Coupled with paternalism is coercion, the threat or use of violence to influence behavior or choice. The august figure in white combined with implied or explicit threats remains a potent force for counteracting patients' wishes. The thrust of modern bioethics is to respect patients by honoring their autonomy (Box 2).

Box 2 Commonly Accepted Societal and Bioethical Values

Autonomy: Self-determination: a person's ability to make personal decisions, including those affecting personal medical care. Autonomy is the opposite of paternalism.
Beneficence: Doing good. A duty to confer benefits. Production of benefit.
Confidentiality: The presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient's permission.
Distributive justice: Fairness in the allocation of resources and obligations. This value is the basis of and is incorporated into society-wide health care policies.
Nonmaleficence: Not doing harm, prevention of harm, and removal of harmful conditions.
Personal integrity: Adhering to one's own reasoned and defensible set of values and moral standards.

Beneficence

At the patient's bedside, beneficence (doing good) and confidentiality (holding information in confidence) have been long-held and nearly universal tenets of the medical profession. Similarly, personal integrity (the adherence to one's own moral and professional standards) is basic to thinking and acting ethically.

Justice

The concept of comparative or distributive justice suggests that a society's comparable individuals and groups should share similarly in the society's benefits and burdens. Many society-wide decisions affecting thoughts and actions about the allocation of limited health care resources are based on this principle. Yet for individual clinicians to limit or to terminate care on a case-by-case basis is an erroneous extrapolation of the perceived need to limit health care resource expenditures.[7] Distributive justice is a social policy concept rather than a clinical model for individual physician-patient decisions.

Truth-Telling

Personal integrity involves adhering to one's own reasoned and defensible set of values and moral standards and is basic to ethical thought and action. Integrity includes a controversial value within the medical community: truth-telling. Some people think that the patient has the right to know the truth, no matter what the circumstances, and have championed absolute honesty. Yet many of these same people, when patients themselves, have been appalled by their physician's lack of sensitivity in relating unfavorable medical news.[12] In this context, being honest does not mean being brutal; truth is best tempered with a modicum of compassion.

Physicians accept a lack of truth-telling, depending on the circumstances. When patient harm may result from failing to disclose the truth, such as happened in the infamous Tuskegee experiments, in which treatment was knowingly withheld from black men with syphilis, it is not only immoral but also probably illegal to withhold the information. Likewise, when failure to disclose information is strictly for the physician's benefit, such as not telling a patient about a dismal prognosis or a medical error, the clinician's behavior suggests serious ethical and legal deficits. Perhaps truth-telling is not universally accepted within the medical profession because of poor role models, lack of training in interpersonal interactions, and bad experiences rather than because the value itself has been discounted. The issues become murkier when truth-telling, or lack thereof, involves a third party, such as a sex partner who has been exposed to an infectious disease.[13]

Confidentiality versus Privacy

Stemming at least from the time of Hippocrates, confidentiality is the presumption that what the patient tells the physician will not be revealed to any other person or institution without the patient's permission.[9] Health care workers have an obligation (duty) to maintain patient confidentiality. On occasion, the law, especially public health statutes, may conflict with this principle because they require physicians to report specific diseases, injuries and injury mechanisms, and deaths. Drug-seeker lists, long used in emergency departments (EDs), can be seen as violations of patient confidentiality, and especially without firm controls on patient entry and clinician access to these lists, they can directly harm patients.[14] Rarely discussed are similar computer lists of previous ED visits that can be easily generated from most ED computer systems. The Health Insurance Portability and Accountability Act (HIPPA) of 1996, a U.S. federal law designed to protect patient

www.ketabpezeshki.com 66485457-66963820

information, however, takes the principle of confidentiality to the extreme, resulting, paradoxically, in greater difficulty in obtaining crucial information needed to treat ED patients.

Privacy, which is often confused with confidentiality, is the right of patients to sufficient physical and auditory isolation that they cannot be seen or heard by others during interactions with medical personnel.[9] ED overcrowding, patient and staff safety issues, and ED design limit patient privacy in many cases.

The increasing use of telemedicine to render advice and to guide procedures at remote sites also places a strain on both patient privacy and confidentiality. Suggested ethical guidelines for such practices can facilitate the use of these new technologies without sacrificing either patient rights or physician duties.[15]

Another recent development has been filming of ED patients for public viewing. Such filming, whether for medical records, education, peer review, or "reality television," encroaches on ED patients' reasonable expectation of privacy and confidentiality because the recording can easily be distributed or misused. Although good reasons exist to allow such filming with patient acquiescence,[16] the standard is now to abstain from such filming for commercial purposes and to require patient or surrogate consent for educational purposes.[17]

MEDICAL AND MORAL IMPERATIVES IN EMERGENCY MEDICINE

Professional Values

Emergency clinicians, in both the out-of-hospital and ED environments, operate with four imperatives: to save lives when possible, to relieve pain and suffering, to comfort patients and families, and to protect staff and patients from injury. All but the last of these are common imperatives of most other clinicians as well, although saving lives may occur more often and more dramatically in EM settings.

Safety: A Unique Value

The last imperative, safety, is nearly unique to EM. In both the out-of-hospital and ED settings, clinicians often encounter dangerous situations in which the environment, the patient, a friend, or a family member poses a threat. Violence against emergency care workers is well documented and unfortunately common. The ED routinely deals with psychotic and intoxicated patients and patients injured in human-on-human attacks, and those involved are often under extreme stress. Although most try to accommodate basic patient rights, clinicians' priority must be their own safety and the safety of their coworkers. This priority does not imply that clinicians should ignore patient safety, but only that they should first ensure their own safety if they or their colleagues are at risk.

CODIFYING PROFESSIONAL VALUES: ETHICAL OATHS AND CODES

Conflicting Principles

In the abstract, bioethical principles often appear simple. However, clinicians adhere not only to basic bioethical principles but also, at least tacitly, to a number of professional, religious, and social organizations' ethical oaths, codes, and statements.[9] This complexity can create a confusing array of potentially conflicting bioethical imperatives. Because bioethical principles seem to be neither universal nor universally applied, the principles that are most patient centered normally hold sway.

Organizational and Institutional Values

Institutions, including health care facilities and professional organizations, have their own value systems. Health care facilities, although relatively well standardized under the requirements of regulatory bodies and government agencies, often have specific value-related missions. Religiously oriented or affiliated institutions may be the most obvious of these, but charitable, for-profit, and academic institutions also have specific role-related values. The values of professional organizations often are set forth in their ethical codes.

Professional Codes

Through the years, the medical profession has codified its ethics more rigorously than any other professional group, incorporating many standard bioethics principles into its ethical codes and oaths. For generations, the existing part of the Hippocratic Oath set the ethical standard for the medical profession.[18] Yet its precepts clash with modern bioethical thinking, and many subsequent professional codes have included what may best be termed economic guidelines and professional etiquette, along with ethical precepts.[19] EP professional values have been incorporated into organization codes, such as the American College of Emergency Physicians' Code of Ethics, and into a more personal oath developed by the Society for Academic Emergency Medicine.[20,21]

Most modern ethical codes do not require a higher level of duty or commitment for members than the same basic moral behavior that is expected of society at large. In fact, many of the ethical issues that would seem to be important to medical specialties usually are not addressed in their codes. Even when topics of interprofessional interactions are excluded, existing medical professional codes differ markedly (Table 2). All, however, try to give a "bottom line"—that is, minimally acceptable—course of action.

APPLYING BIOETHICS

Emergency Physician–Patient Relationship

The EP has a markedly different relationship with patients from that of other health practitioners, especially those providing primary care[22-24] (Table 3). EPs care for patients who are unfamiliar to them and to the institution. Practitioners who either know their patients or who care for them in less acute settings often have the time and the mechanisms to make sound ethical decisions, but EPs have more limited options. A suggested method for rapid, ethical decision-making in the ED setting is outlined in Box 3 and discussed in a later section.[25]

Recognizing Ethical Problems

Although physicians like to reduce all clinical situations to "medical problems," today's increasingly complex medical environment often produces problems that are inexorably intertwined with fundamental bioethical dilemmas. Some are obvious, but many are more difficult to recognize.

Prioritizing Conflicting Principles

Once such dilemmas are recognized, applying bioethical principles to clinical situations can be confusing. When two or more seemingly equivalent principles or values seem to compel different actions, a bioethical dilemma exists. This situation is often described as being "damned if you do and damned if you don't," in which any potential action appears, on first reflection, to be an option between two seemingly equivalent goods or evils. In the following real case, taken from the book *Ethics in Emergency*

www.ketabpezeshki.com 66485457-66963820

Table 2 Comparison of Six Ethical Codes for Physicians

PRINCIPLE OR CONCEPT	SAEM	ACEP	EMRA	AMA	AOA	HIPPOCRATIC OATH
Protect patient confidentiality		×	×	×	×	×
Maintain professional expertise	×	×	×	×	×	×
Committed to serve humanity	×	×	×	×	×	
Patient welfare primary concern	×	×	×	×		×
Considerate to patients, colleagues	×	×	×	×		×
Respect human dignity	×	×	×	×		×
Safeguard public health	×	×	×	×		×

ACEP, American College of Emergency Physicians; *AOA,* American Osteopathic Association; *AMA,* American Medical Association; *EMRA,* Emergency Medicine Residents' Association; *SAEM,* Society for Academic Emergency Medicine.

Medicine, the attending physician can be said to be on the horns of a dilemma (involving two prickly but seemingly equal choices): although only two options for action may be available, both options involve a number of conflicting bioethical principles.

Case Example: Conflicting Bioethical Principles

A 60-year-old man stabbed himself in the abdomen because of intractable pain from terminal pancreatic cancer, unrelieved by any medical therapy. A well-meaning friend, who happened to be in the house when the event occurred, called the paramedics, who brought him to the ED. Although the man will obviously bleed to death if he is not given aggressive care, neither the patient, who is still alert and oriented, nor his wife, who is present, wants any treatment other than pain control. A review of his chart confirms that his physicians are at a loss as to how to alleviate his pain and that he is expected to die within the next several weeks.[26] The physician believes in respecting a patient's autonomy yet usually questions patients' decision-making capacity when they attempt suicide. Such patients' actions seem to raise the question of whether, in fact, they have a right or an ability to be autonomous. This physician also believes strongly in beneficence: helping those in need, relieving pain, and saving lives when possible. Beneficence suggests two alternative courses of action: palliative care or aggressive therapeutic intervention. Merely using analgesics and other comfort measures will abet a suicide; initiating aggressive medical and surgical interventions will prolong a dying process that the physician's colleagues have found to be unresponsive to even palliative treatment. Which value takes precedence: patient autonomy or beneficence? If beneficence predominates, should it be aimed toward relieving suffering, prolonging life, or a third option that could include both? Bioethics deals with problems that are neither black nor white—only gray.[27]

MEDICAL IMPERATIVES AND BIOETHICAL DILEMMAS

Clinicians have their own ethical values, as do professional organizations and health care institutions. Conscience clauses permit clinicians to "opt out" when they believe that they have a moral

www.ketabpezeshki.com 66485457-66963820

Table 3 Relative Differences between Emergency Practice and Primary Care Practice

ED SETTING	PRIMARY CARE SETTING
Patient often is brought in by ambulance, police, or family.	Patient chooses to enter medical care system.
Patient does not choose physician.	Patient chooses physician.
ED personnel should gain patient's trust.	Physicians and nurses already enjoy patient's confidence and trust.
ED personnel do not know patient, family, values.	Physicians and nurses often already know patient, family, values.
Patient experiences an acute change in health status.	Patient has chronic medical problems.
Anxiety, pain, alcohol, and altered mental status are common.	Anxiety, pain, alcohol, and altered mental status are less common.
Decisions are made quickly.	There is usually time for reflection and deliberation.
Physician makes decisions independently.	Physician has greater opportunity to consult with patient, family, other physicians, ethics committees, lawyers, courts, ethicists.
Physician represents institution and medical staff.	Physician represents self or medical group.
Work environment is open and less controlled.	Work environment is private and controlled.
ED personnel frequently have a stressful work schedule.	Work schedule often is set or canceled by physician.

Box 3 A Rapid Approach to Ethical Problems in the Emergency Department

Is this a type of ethical problem for which you have already worked out a rule, or it is at least similar enough that the rule could reasonably be extended to cover it?

- YES
  Follow the rule.
- NO
  Is there an option that will buy you time for deliberation without excessive risk to the patient?
  - YES
    Take that option.
  - NO
    1. Apply Impartiality Test.
    2. Apply Universalizability Test
    3. Apply Interpersonal Justifiability Test.

Modified from Iserson KV: An approach to ethical problems in emergency medicine. In Iserson KV, Sanders AB, Mathieu D (eds): Ethics in Emergency Medicine, 2nd ed. Tucson, Ariz, Galen Press, 1995.

conflict with professionally, institutionally, or legally required actions. These conflicts, which may have a religious, philosophical, or practical basis, pose a barrier to use of the normal ethical decision-making algorithm. When such conflicts exist, it is morally and legally acceptable, within certain constraints, for the physician to follow a course of action based on his or her own value system. The constraint generally requires that timely and adequate medical care be provided for the patient, which may be particularly difficult to achieve in EM. When conflicts over values exist, however, it is essential for the practitioner to recognize the patient's identity, dignity, and autonomy to avoid the error of blindly imposing personal values on another.[9]

Professional Value Conflicts

The imperative to save lives causes the most conflict between EPs and other clinicians. EPs recognize that some of the intubations and resuscitations they perform will be unwanted by patients or surrogates. Nearly all EPs have on occasion been berated by an irate intensivist or private practitioner for resuscitating a patient "who should not have been resuscitated." Nevertheless, the lifesaving imperative begins when the ambulance is called.

One classic dilemma is that posed by the exsanguinating adult patient, awake and still with medical decision-making capacity, who explicitly states a refusal to accept any blood or blood products based on religious beliefs. The physician, with a professional duty and moral commitment to preserve life, does not agree with the patient's decision. Yet society (through the benchmark of court decisions) has repeatedly sided with the patient. In this case the patient's autonomy and right to practice his or her religion are recognized as the over-riding values. The case becomes less clear when the patient does not have decision-making capacity, is a minor, or appears to be under external pressure to make a life-threatening decision.

Other examples of ethical problems and conflicts in emergency medical care include uncertainty about resuscitation efforts, especially when patients and families may not want such efforts; teaching, particularly in critical situations or using procedures performed on the newly deceased; emergency medical system (EMS) control, when administrative rules and good patient care conflict; helping others when one's own life may be placed at risk; and patient access, such as limited financial and personnel resources in the face of obvious patient need. Even if these problems do not fit into the classic form of a dilemma, they may be recognized as bioethical problems because they require the clinician to make a choice between two (or more) accepted values.

RAPID ETHICAL DECISION-MAKING MODEL

The rapid ethical decision-making method of ethical case analysis, described in Box 3, is designed as a way of avoiding an ethically incorrect course of action for the EP in need of a fast answer to an ethical dilemma. A decision based on a known precedent—the first step—is the most productive way to use this method. However, such decision-making requires advance planning, in-depth reading, and thought regarding ethical problems. Just as with the indications for any emergency procedure, EPs should at the very least be prepared with a course of action for the most common ethical dilemmas they may face in the ED.

Even the prepared clinician, however, can encounter cases without relevant known precedents. With no precedent to rely on and no way to "buy time," the practitioner should select a possible course of action and test it for ethical validity. In such instances, three tests—the impartiality test, the universalizability test, and the interpersonal justifiability test—can be used. The *impartiality test* asks whether the practitioner would accept this action if he or

Box 4 Guidelines for Development of an Out-of-Hospital Advance Directive Policy

Policy Scope

To ensure maximum coherence and compliance, a comprehensive out-of-hospital DNAR policy should be endorsed by the widest possible jurisdiction, comprising local, regional, and state agencies and the medical community, including the EMS governing body. Whenever feasible, legislative support for such a policy should be sought.

Policy Guidelines

1. Note the established fact that current basic and advanced life support interventions may not be appropriate or beneficial in certain clinical settings.
   - Develop a means to educate the public about the appropriate use of 911 after expected deaths.
   - Establish the fact that comfort care and palliative care are affirmative actions for patients with DNAR orders. These appropriate interventions, including hospice and respite care, do not require EMS activation and often can be arranged by calling the patient's physician in anticipation of death.
   - Develop a means to educate health care workers on topics of advance directives, including information on local out-of-hospital DNARs, community hospice alternatives, and bereavement services.
2. Establish consensus on the ideal identification device for DNAR directives to ensure continuity of care across settings.
3. Reiterate that initial resuscitative attempts usually are indicated when the patient's wishes are not known.
4. Define the conditions under which an out-of-hospital DNAR order can be considered, including its use in long-term care settings and in the emergency department.
5. Define which patients have the decisional capacity to agree to a DNAR order and whether surrogates can sign such orders.
6. Establish a mechanism to determine the precedence of various directives, including living will, durable power of attorney for health care, and out-of-hospital advance directive (i.e., DNAR order).
7. Develop a statutory prioritized list of surrogates to be used when there are no advance directives and the patient's decisional capacity is impaired.
8. Consider language acknowledging the growing home hospice movement as it concerns children, and incorporate provisions for document use in minors.
9. Establish that the decision not to attempt resuscitation must be an informed decision made by the patient or the surrogate.
10. Identify the information that should be contained in the DNAR order and the authority that will be responsible for development of such a mechanism.
11. Identify the clinical procedures that are to be provided and those withheld in the adherence to the DNAR order, or specify the authority that will verify adherence.
12. Define the exact manner in which the DNAR order is to be followed, including the role of online medical direction. Each system should ensure that a communication path to access online medical direction is immediately available, when necessary.
13. Establish legal immunity provisions for those who implement DNAR orders in good faith.
14. Establish data collection and protocol evaluation to perform periodic operational assessments.
15. Identify permissible exceptions to compliance with DNAR out-of-hospital directives. For example:
    - The patient is able to revoke a written directive at any time.
    - The EMS personnel can cancel the out-of-hospital DNAR order if there are doubts about the document's validity.

Adapted from Schears RM, Marco CA, Iserson KV: "Do-not-attempt-resuscitation" (DNAR) policy in the out-of-hospital setting. Ann Emerg Med 44:68, 2004.
DNAR, do-not-attempt-resuscitation; *EMS,* emergency medical services.

she were in the patient's place. In essence, this is a form of the golden rule. The *universalizability test* asks whether the practitioner would be comfortable having all practitioners perform this action in all relevantly similar circumstances. This involves generalizing the action to all colleagues and then asking whether a rule for the contemplated behavior is reasonable. The *interpersonal justifiability test* asks whether the practitioner can supply good reasons to others for the action. Will peers, superiors, or the public be satisfied with the answers? If the answer to the question posed in each of the three tests is affirmative, the practitioner has identified a reasonable probability that the proposed action falls within the scope of ethically acceptable actions.[25]

ADVANCE DIRECTIVES

The ethical principal of patient autonomy is the foundation for a range of documents that outline what care a patient wishes to receive if he or she is no longer able or competent to directly communicate those values. The term *advance directive* describes several types of legal and quasi-legal documents. Advance directives usually are written to avoid prolongation of an inevitable, often painful or nonsentient dying process. However, they can also be used to instruct surrogates and the patient's medical team to "do everything," whenever possible. Advance directives include the living will, durable power of attorney for health care, prehospital advance directive (Box 4), and mental health advance directive. Do-not-attempt-resuscitation (DNAR), do-not-hospitalize, and out-of-hospital DNAR orders are not considered to be advance directives but rather are physician orders because they are not patient or surrogate initiated. All play a role in EM.[28,29]

Advance directives, DNAR orders, and other end-of-life considerations are discussed in the End of Life chapter.

CONSENT, DECISION-MAKING CAPACITY, AND SURROGATE DECISION MAKERS

Respect for patients, the basis for patient autonomy, requires that adults consent before undergoing medical interventions. To give consent, they must retain decision-making capacity. When patients cannot make their own health care decisions, others need to make such decisions for them. In such situations, three questions arise: What does "consent" mean in the ED? How can clinicians determine when patients lack such capability? Who then makes the decision?

Consent

Patients can provide three forms of consent: presumed, implied, and informed. Many patients may provide all three types of consent at different times during a single ED visit. Because clinicians use all three types of consent in EDs, and all are ethically and legally valid, clarifying the differences between them is in order.[30]

The concept of *presumed consent* most commonly applies when patients are informed of what will occur and they do not refuse

www.ketabpezeshki.com 66485457-66963820

treatment. They allow themselves to be rolled on a gurney to the radiology suite to have a urethral catheter placed, and they remain still while being sutured. The more dramatic ED scenario involving presumed consent is the arrival of moribund patients with grave, often unstable conditions for which a reasonable person would be expected to want treatment. In those cases, clinicians "presume" that rational patients would want treatment. A question that must be raised, however, is whether those patients would want interventions even in the absence of a reasonable chance for meaningful (from the patient's standpoint) survival. Futility often is discussed from the clinician's perspective (see Futility later in the chapter); whether patients would give consent in these circumstances raises the question from the more valid patient's perspective.[30]

Implied consent is operative when patients actively cooperate with the procedure, such as when they extend the arm for phlebotomy or lift the blouse so that leads can be placed for electrocardiography.[30] Working under presumed or implied consent does not signify absence of patients' concern about the procedure or its complications. Rather, patients may (1) believe they know enough about the procedure to permit it or to cooperate with it without further questioning, (2) be in a condition (e.g., unconscious) in which they are unable to communicate, or (3) feel too afraid (e.g., of the clinician or hospital authority) or uncomfortable (e.g., because of a language barrier) to ask.[30]

Informed consent assumes that a patient who has decision-making capacity (e.g., has been given all pertinent facts about the risks and benefits of a particular procedure) understands the risks and benefits and voluntarily agrees to undergo the procedure.[30] Even if a patient with decisional capacity does not ask about a complex or potentially dangerous procedure, the clinician is obligated to provide information about the associated risks and benefits, unless the patient specifically asks not to be told. In those cases, the patient should be asked if he or she would like a relative or friend present in the ED to be told. This person need not be the patient's surrogate but may later help explain what occurred to the patient.[30]

Informed consent relates to both law and ethics. Respect for persons is the requirement's ethical bulwark; statute and common law provide the legal rationale. Physicians have a professional and moral obligation to provide their patients with the information necessary to make informed decisions. Communicating honestly with patients so that they may participate in decision-making is a recent rather than historical imperative. On the basis of a respect for patients, this cooperative physician-patient relationship reverses the paternalism that, since Hippocratic times, has guided physician interactions with patients.[30,31]

Virtually all states, either in statute or by common law, now require physicians to inform patients about treatment choices and the associated risks and benefits. The legal standard for the information provided is either the community standard (also known as the professional community standard or the reasonable physician standard) or the materiality standard (also known as the reasonable or prudent or subjective patient standard). The former asks: What would a prudent physician in the same community, with the same background, training, and experience, have disclosed to a patient in the same or similar situation? The latter asks: What would a reasonable patient in the same or similar situation need to know to make an appropriate decision?[30,31]

Note that great variability exists in the legal requirements. For example, although most of the nation's EDs require informed consent for many regional anesthetic blocks, closed fracture reductions, abscess incision and drainage, lumbar punctures ("spinal taps"), injection of radiocontrast agents and radionuclides for radiography, and nonemergency thoracostomy (chest tube placement), Texas statutes eliminate any requirement to disclose the specific risks or hazards before these procedures are performed.[30,32]

Decision-Making Capacity

Many ethical dilemmas in emergency medical care dissolve on ascertaining the patient's decision-making capacity, often linked with consent to (or, more commonly, refusal of) a medical procedure. A basic canon of both ethics and law, as stated by Justice Benjamin Cardozo, is that "[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body."[33] These situations can often be clarified by an appreciation of what is meant by decision-making capacity and how it relates to consent.

EPs must be prepared to decide quickly whether patients lack decision-making capacity. Although a lack of capacity is obvious in the unconscious or delirious patient, it often is less apparent when the patient remains verbal and at least somewhat coherent. Because such decisions in emergency situations are often time sensitive, unlike in other medical venues, bioethics consultations may not be readily available.

In clinical practice, the word *competence* is often used to mean *capacity*. *Competence* is a legal term and can be determined only by the court. *Capacity* refers to a patient's ability to make decisions about accepting health care recommendations. Capacity is always decision relative rather than global. Although an inebriated person can have the capacity to refuse to have a small laceration sutured, especially if there is evidence of prior refusal without remorse, the same person may not have the capacity to agree to an elective operation or to refuse to have an emergent lifesaving procedure or operation. To have adequate decision-making capacity in any particular circumstance, the person must understand the options, the consequences of acting on those options, and the costs and benefits of consequences in relation to a relatively stable framework of personal values and priorities[34,35] (Box 5). Disagreement with the physician's recommendation is not in itself grounds for determination that the patient is incapable of making a decision. In fact, even refusal of lifesaving medical care may not prove the person incapable of making valid decisions if it is done on the basis of firmly held religious beliefs, as in the case of a Jehovah's Witness patient who refuses a blood transfusion.

Surrogates

If patients lack capacity to participate in some decisions about their care, surrogate decision makers should then become involved. In most locales, the patient's advance directive may designate surrogates, or such persons or agencies may be detailed in institutional policy or law. Surrogates often include spouses, adult children, parents (of adults), and others, including the attending physician. On occasion, bioethics committees or the courts will need to intervene to help determine the decision maker.

Children represent a special case. Persons younger than the age of majority (or unemancipated) are usually deemed incapable of

Box 5 Components of Decision-Making Capacity

- Knowledge of the options
- Awareness of consequences of each option
- Appreciation of personal costs and benefits of options in relation to relatively stable values and preferences*

Modified from Buchanan AE: The question of competence. In Iserson KV, Sanders AB, Mathieu D (eds): Ethics in Emergency Medicine, 2nd ed. Tucson, Ariz, Galen Press, 1995.

*As part of the assessment for capacity, the patient should be asked about why he or she made a specific choice.

www.ketabpezeshki.com 66485457-66963820

making independent medical decisions, although they are often asked to give their assent to the decision, allowing them to "buy in" to their medical treatment plan. In many cases, in determining whether a child has decision-making capacity, the same rules as those that apply to adult capacity are used. The more serious the consequences, the more the capacity to understand the options, consequences, and values involved is required of children to make a decision.[9]

In the relatively rare case in which a patient has a court-appointed guardian for health care decisions, the guardian's decisions supersede those of both the patient and any other surrogates. Even if a parent is present, it is not always clear that the adult is acting in the best interest of the child. In such cases, child protective services may need to become involved. Disagreements between parents may, in extreme cases, require the involvement of bioethics committees or the courts.

Family

Traditionally, and usually in practice, the family, in particular the spouse, acts as a surrogate decision maker when the patient does not have the capacity to make medical decisions. Yet even when there is a strong family tie, emotional or fiscal costs may sway the surrogate decision maker from certain courses of action the patient would wish taken.

Surrogates make decisions on the basis of two distinct patterns: substituted judgment and best interests. *Substituted judgment* is used when there is an assumption that the surrogate knows enough about the patient's values to make a decision similar to that which the patient would make. It is not clear that anyone knows that much about a person to make decisions in every situation.[36,37] Surrogates use the *best interest* standard when they do not know what the patient would want done in a particular situation, but as in the case of Karen Ann Quinlan, in which life-prolonging measures were eventually discontinued against the wishes of some family members, they can use earlier statements and behavior to document the patient's values and then make a decision.[38] Some states may require explicit written directives for surrogates to follow.[39,40] The best interest standard also applies in cases in which the patient has never had adequate decision-making capacity, as in the Saikewicz case, in which a court-appointed guardian for an elder who lacked decision-making capacity decided against treatment for leukemia after consultation with medical specialists because of a low likelihood of success in the face of debilitating side effects of treatment.[41] Unless there is already a court-appointed guardian, these situations often end up in court.

Surrogate Lists

If a patient lacks decision-making capacity and has no advance directive, many states stipulate that another person may automatically become the person's surrogate. In practice, this almost always means that the patient's spouse may act in that capacity. Some states now have a statutory surrogate list to simplify the process. The most extensive of such lists, which has worked well for nearly two decades, specifies surrogates in the following order: spouse (not divorced or legally separated), a majority of the adult children who can be reasonably contacted, parents (of an adult), domestic partner, sibling, close friend, and attending physician in consultation with a bioethics committee.[42]

Bioethics Committees and Consultants

Multidisciplinary committees have been developed in most large hospitals to consult on cases with bioethical dilemmas and may also participate in surrogate decision-making.[42] These committees usually have three main functions. First, they coordinate education on bioethical issues involving clinical care for the committee members, hospital physicians and staff, patients, families, and the local community. Second, they help institute mandatory or suggested policies or guidelines for health care professionals regarding decision-making processes in problematic cases and resource allocation. Third, they consult prospectively and retrospectively on clinical cases and offer advice and conclusions to those directly involved, most often concerning the treatment or nontreatment of patients who lack decision-making capacity. Ethics committees usually do not act as the primary decision makers. Rather, the members serve as consultants, providing information, advising, and supporting the primary decision-making role of the patient-family-physician triad. A common consultation relates to urgent decisions about withholding, withdrawing, or continuing life-sustaining medical care. A large part of ethics committee work consists of clarifying the facts and fostering communication.[43] In 1995, the Joint Commission (formerly the Joint Commission for the Accreditation of Healthcare Organizations [JCAHO]) began requiring hospitals to ensure that ethics committees perform their functions.[44]

Physicians

In the past, physicians made unilateral decisions for their patients, regardless of whether the patients had the capacity to decide for themselves. This still occurs, of course, especially for the acute illnesses and unexpected injuries seen in EDs. There is a tendency for physicians to determine that a patient does not have the capacity to make medical decisions simply because the patient disagrees with the clinician. If the patient's decision-making capacity is questioned in the ED, the clinician is often forced to make a decision without assistance. But when it is possible to buy time, clinicians should consult with colleagues and, if possible, the hospital's bioethics committee (see Box 3). When making unilateral decisions, physicians should recognize that they are not omniscient. Prognoses are often incorrect and medical knowledge is finite.

Courts

The courts often act as the final adjudicators of disagreements over medical care. They appoint legal guardians and, in a few select cases, set precedent that is followed as health law. The courts, however, usually are neither expeditious nor necessarily cognizant of bioethical principles. They are instructed only to follow the societal values codified in the law. Many courts have suggested that whenever possible, health care decisions should remain at the bedside rather than in legal chambers.[38-40]

RESUSCITATION ETHICS

The most time dependent of all activities, and arguably the best training periods in the ED, occur during resuscitations. The patients who require this care have implicitly been guaranteed that all appropriate medical knowledge and skill will be brought to bear in the attempt to save their lives. This implied promise leads to a dilemma. If the most proficient ED professional always leads the resuscitations and performs procedures, the patient will receive the maximum beneficence, as well as nonmaleficence, as expected. Yet restricting ED practice in this manner also deprives future patients of trained clinicians who could bestow the same beneficence.

This controversy has raged for many years. The appropriate balance seems to be that training in EDs can ethically proceed, as it does in other areas of medicine, if safeguards are provided in the form of on-site supervision by experienced clinicians to ascertain that the patients receive the best possible and most

www.ketabpezeshki.com 66485457-66963820

appropriate care. It also has been suggested that medical students and residents be certified for cognitive and procedural skills in a manner similar to that of other hospital physicians. This certification would enable faculty to know when trainees are capable of performing resuscitations, as well as other medical procedures, on their own.[45]

Rarely discussed, but a common practice in some teaching hospitals, has been the custom of allowing trainees with little skill or knowledge to learn and to practice procedures on those undergoing resuscitation only when a patient is deemed "unsalvageable."[46] This practice does a disservice to the patient because prolongation of resuscitative attempts solely for this purpose may lead to a clinical state that prolongs dying. It also harms the family and society by making them pay for unnecessary procedures. (It may actually be less problematic to practice and to teach once a patient is dead because the patient cannot be harmed and the family does not pay for these activities. See Postmortem Teaching later in the chapter.)

Futility

EPs, nurses, and EMS personnel may, in some circumstances, believe that further medical interventions are "futile." Yet only three situations meet the most commonly accepted definition.[47] The first such situation, which clinicians can identify in only a limited set of circumstances, is that in which the intervention is effective in less than 1% of identical cases, based on the medical literature. ED thoracotomy for blunt trauma is a well-documented example. Another common scenario with very low survival rates is that of the out-of-hospital cardiac arrest, either unwitnessed or in a patient who arrives from a long-term care facility.[48] Individual clinicians should not rely on their own experiences to make such decisions, however, because they often are skewed owing to selective memory, limited numbers of similar cases, and other biases.

The second futile situation is physiologic futility, in which known anatomic or biochemical abnormalities will not permit successful medical interventions. Examples of such abnormalities generally accepted by emergency medical systems as reasons not to intervene or to provide transport to hospitals are rigor mortis (muscle contraction after death), algor mortis (lowering of body temperature after death), burns so severe that the victim is beyond recognition, and injuries incompatible with life (e.g., decapitation). These along with prolonged normothermic resuscitative attempts without success or prolonged "down time" with an isoelectric electrocardiogram and pulseless electrical activity are the criteria often used to help determine whether EMS personnel can pronounce death on the scene. In these instances, EMS need not expend valuable resources in a futile resuscitative effort.

The third situation is that in which the proposed intervention will not achieve the patient's goals for medical therapy in accordance with the patient's values. Recognizing this instance, the American College of Emergency Physicians asserts, "Physicians are under no ethical obligation to render treatments that they judge have no realistic likelihood of medical benefit to the patient."[49] Because this course of action is based on knowing the patient's values related to medical treatment, it is necessary to have talked with the patient in advance (rare in the ED setting), to have received surrogate-supplied information or decisions, or to have access to the medical record. The danger is that differences in values between caregivers and patients may lead to overtreatment or undertreatment. Communication, if necessary with use of a third party, may help resolve these issues.

The futility concept should never be used to deny care to dying patients. Even terminal patients experience medical emergencies that require intervention. The goal is to ease pain and suffering. How that is accomplished depends on the patient, the medical condition causing discomfort, and the patient's value system.

Withholding versus Withdrawal of Treatments

In EM, a significant difference *rightfully* exists between the withholding and the withdrawal of life-sustaining medical treatment. The justification for this distinction stems, in part, from the nature of the practice of EM and the unique manner in which EPs apply many ethical principles. Because EPs often lack vital information about their patients' identities, medical conditions, and goals for medical treatment, withholding of emergency medical treatment is more problematic than is later withdrawal of unwanted or useless interventions. Owing to the nature of EM, in both out-of-hospital and ED settings, higher standards are required to withhold medical treatment than to withdraw it.[50]

Physicians should begin or continue resuscitation of those patients who arrive at the ED without sufficient evidence to determine that the resuscitation effort will be unsuccessful. The only reason to *withhold* cardiopulmonary resuscitation (CPR) is the availability of clear evidence, such as a standard advance directive, that the patient did not wish to have this done or of clinical evidence that further efforts would be futile.[51] Without such information, the presumption must be to intervene.

Once the EP obtains information confirming a patient's wish not to be resuscitated or indicating a medical condition not amenable to resuscitation, resuscitative efforts and other medical treatment may appropriately be withdrawn. This information may be obtained from an advance directive, a patient surrogate, recent documentation in the medical chart, or EMS communication detailing the failed results of the ongoing resuscitative effort. With rare exceptions, such as after failed suicide attempts, resuscitative efforts should be withdrawn when information is provided either that the patient did not want such efforts or that the patient's medical condition precludes success.[52,53]

Many factors influence the potential success of resuscitative efforts, including time to CPR, time to defibrillation, presence of comorbid illness, pre-arrest clinical status, and initial arrest rhythm. No combination of these factors, however, clearly predicts the outcome.[54,55] The most important factor associated with poor outcomes is the *duration* of unsuccessful resuscitative efforts.

The possibility of a successful resuscitation becomes clearer as time progresses; a patient's chance of being discharged from the hospital alive and neurologically intact diminishes if spontaneous circulation does not return after 10 minutes of intensive resuscitative efforts.[56-59] Malpractice concerns have led some physicians to prolong all resuscitation attempts until they reach the point at which there have been no survivors.[54] In reality, cardiac resuscitation with properly executed advanced cardiac life support interventions and documented asystole should not last more than 30 minutes and usually should end much sooner, except in unusual circumstances, such as with pre-arrest hypothermia, after some drug-induced events, after lightning or electrical shocks, or in infants or children with refractory ventricular fibrillation or tachycardia.[54,59-64] Without these mitigating factors, prolonged resuscitative efforts are unlikely to be successful.[30]

Three special situations should be noted:

1. Cardiac arrest from blunt trauma is nearly uniformly fatal, so little benefit derives from performing chest compressions for any extended period after the airway is secured.[65]
2. When health care resources are limited, such as during disasters, available resources, such as time, personnel, and equipment, should be devoted to treatment of those patients with the greatest chance of benefiting. This principle may lead to withholding or more rapid discontinuation of resuscitative efforts than is standard in normal practice.
3. It is unethical to prolong resuscitative efforts to practice or to teach procedures or to complete research protocols.[53]

www.ketabpezeshki.com 66485457-66963820

Palliative Care

Although lifesaving medical interventions may not be appropriate in all cases, EPs, whenever possible, should provide patients with palliative care. Terminally ill and fatally injured patients have the right to receive state-of-the-art palliative care.[66] Palliation often includes analgesics and may include diuretics, sedation, oxygen, paracentesis or thoracentesis, and other medications or procedures to alleviate suffering. Medical personnel should never withdraw or withhold care; only treatment should be withheld when it is appropriate. Although medical practitioners, surrogate decision makers, and sometimes patients find it emotionally easier to forgo new interventions than to withdraw ongoing treatment, no orders, policies, or directives should ever prevent EPs from alleviating discomfort.[1]

The purpose of palliative interventions is not to prolong the dying process but rather, when death is inevitable, to make it as comfortable as possible for the patient. As patient advocates, EPs may need to "push" to have the patient admitted to a hospital, hospice, or nursing home or to get ancillary personnel (e.g., social workers, home health nurses) to intervene for the patient.[1]

Notifying Survivors

Death, especially when it is sudden and unexpected, shocks and devastates family and friends. For them, it is a life-changing event, with every nuance burned into their memories. Moreover, although they may not consciously acknowledge it, such losses may deeply affect ED personnel, despite their almost constant exposure to life's disasters. This makes death notifications and dealing with the survivors both vitally important and extremely difficult. EPs, who deal with sudden death on a daily basis, are in a position to gain considerable knowledge of and to hone their skills in how to care for the survivors, their newest patients.[67]

Even though notification of survivors of a sudden, unexpected death is one of the most difficult parts of the job for EPs, they and other professionals whose job includes delivery of news about sudden, unexpected deaths are rarely taught the skills necessary to perform this task. Notification of survivors is emotionally draining; 70% of EPs find death notifications to be personally difficult. Perhaps this is because only half received any type of death-notification education in medical school, and only one third received any such training during residency.[68]

On occasion, physicians give the job of death notification to residents, medical students, or nurses. Although all three groups should be present to learn the techniques involved, to have an opportunity to hear what is said, and to observe an attending physician showing sensitivity, they should not be left to do death notifications on their own. That is a form of professional abandonment and, in a teaching hospital, the worst form of student abuse.[69]

Viewing of Resuscitations

Traditionally, survivors have not been permitted to view resuscitation attempts.[67] That attitude, however, is gradually giving way to a more enlightened view based, in part, on recognition that families gain enormous psychosocial benefits from being present and that they are also patients in need of appropriate support.

The argument against allowing survivor onlookers has been that resuscitations often involve large teams, unclear communications, and team leaders who are unwilling or unable to make firm, timely, and rational decisions.[70] Having family members present, the argument goes, introduces the possibility of an onlooker's fainting or otherwise becoming another patient. Survivors frequently misinterpret the team's discussions or actions, and team members may feel uncomfortable having family members judging their actions.

Yet studies in both the United States and Britain have shown that nearly all survivors who witnessed ED resuscitative efforts found the experience helpful. Seventy-six percent of survivors responded that their grieving was facilitated by having witnessed the resuscitation, and 64% thought that their presence was helpful to their dying family member.[71] Psychological tests of survivors who witness resuscitation attempts, performed at 3 and 9 months after the event, showed that this group experienced fewer episodes of "intrusive imagery," such as flashbacks of the events leading to the death, compared with survivors not present at the resuscitation (relatives in the control group). They also had lower levels of anxiety, depression, post-traumatic avoidance behavior, and grief.[72]

The American Heart Association now endorses giving family members the opportunity to be present so long as the patient has not previously objected. This position stems from the benefit families can derive from their presence during resuscitation attempts, the lack of harmful effects on them from viewing these resuscitations, and their quasi-right to be there based on the nature of their relationship to the patient.[53,73]

The presence of these survivors does not hinder the resuscitative efforts and often leads to quieter, more effective team efforts. Experience has shown that survivors who witness ED resuscitative attempts never question whether the team "tried hard enough," do not ask whether the person is *really* dead, and spend less time in the ED trying to come to terms with the death. In addition, survivors may actually thank the ED team for their efforts, a situation that rarely occurs under other circumstances, and the ED staff never has to "notify" survivors of the death.

The general procedure is as follows:

Ask survivors if they want to view resuscitative efforts.

If they do, give them a quick briefing about what they will see, and have a knowledgeable staff member, usually a chaplain, social worker, or ED nurse who can answer their questions, accompany them.

Provide a chair for elders and allow survivors to leave and to reenter as they wish.

Staff should attempt to cover as much of the patient as is compatible with effective resuscitative efforts.

Team members should be advised that family is in the room.

The survivors should be encouraged to talk to and to touch the patient.

Decisions to pronounce the patient dead, although often discussed with the family, generally are communicated in the format of advising them that "we must stop now." They should never be asked whether to stop the resuscitative effort; this is a medical decision.

If the family is present when it is clear that resuscitative efforts should cease, the situation should be explained to the family before supportive measures are discontinued. This provides them with a chance to "say good-bye" before death is pronounced. Dedicated pediatric EDs and pediatric resuscitation units in general EDs have adopted these procedures more often than others.

Postmortem Teaching

A less commonly discussed aspect of EM education programs is the use of recently deceased patients to teach or to practice emergency procedural techniques, such as intubations and central line placement. Although whether this practice is ethical is a matter of controversy, a reasonable argument might be that if medical treatment could not save the patient, then the EP's responsibility is to hone skills for the next patient in need of expertise in resuscitative techniques. This is not to condone the desecration of a body. Rather, it suggests that because clinicians learned the techniques

www.ketabpezeshki.com 66485457-66963820

used during the attempted resuscitation on other dead or living patients, this (now dead) patient owes the next patient the same courtesy. No one would advocate practicing of unneeded procedures on living patients, and many people argue against use of experimental animals. The religious or ethical beliefs of some ED personnel may make practicing or teaching of these procedures in such circumstances problematic.[74-77]

Resuscitation Research

Physicians in a new and advancing specialty have an obligation to advance the knowledge base from which they practice. This can be done only through research, a significant component of which should necessarily be clinically based. In the United States, federally mandated institutional review boards (IRBs) must approve any research involving human subjects, including research in EDs and, possibly, in prehospital care.[78] Increasingly, research ethics committees are being used to approve human subject research throughout the world. The IRBs try to guarantee that patients who are asked to participate in research review and sign an adequate informed consent document. Yet, even if the patient is conscious, it is unclear whether truly free and informed consent can be given in the midst of a medical emergency.[79] In both trauma and cardiac resuscitation research, informed consent is, of course, not feasible. It is usually difficult if not impossible to obtain retrospective patient or, if appropriate, prospective surrogate consent. So as not to deny critically ill and injured patients the opportunity to participate in possibly beneficial research trials, the U.S. Food and Drug Administration and the Department of Health and Human Services issued regulations, which became effective in 1996, that allow "emergency research" without informed consent. These regulations contain extensive patient safeguards, including community consultation, public disclosure, and intensive oversight.[80]

The ethical and legal basis for these regulations is presumed consent: if the research is not harmful, and especially if it is potentially helpful, most "reasonable" patients would acquiesce to the research, given the basic values of good and evil (see Box 1).[81-83] As routinely occurs in EM practice, persons suffering unexpected adverse events with a high probability of rapid death or serious morbidity generally demand that the physician deliver acute care interventions—immediately and without discourse. If there is a chance that the patient could benefit from a therapeutic course of action in such circumstances, most people would demand that it be used. Similar logic applies with acute care research, especially when accepted or standard therapy is futile and possibly when the investigators believe that equipoise (therapeutic equality) exists between the two tested forms of therapy. Protection for the patient in these cases rests with IRBs, which, among other considerations, must guard against the possibility of organ-specific success but failure to benefit the entire person, such as producing a patient in a persistent vegetative state after "successful" CPR.

Beyond IRB authorization for research is a moral responsibility for the individual researcher to ensure that the research protocol and its execution are ethical. This responsibility extends to the journals in which the research is published.[84] In the main, EM has an excellent record of ethical research.[85]

PUBLIC POLICY AND BIOETHICS

Restricted Access to Emergency Medical Care

Society has acknowledged its moral obligation to ensure that everyone has reasonable access to adequate health care.[86] People's need for health care is unequally distributed and highly unpredictable. Few could afford this care if left to their own devices, so mechanisms are in place to share the risk.[87]

The ethical dilemma for EPs comes in basically two forms: one precipitated by the institution in which the ED is housed and one by outside third-party payers. Some institutions have refused care to patients coming to the ED, sending some away for clinic appointments at a later time.[88] Institutions also have pressured EPs to limit treatment, ancillary tests, or hospital admission for patients without the ability to pay. Although such limitation may seem patently immoral, another question should be asked: Is there a moral obligation to the community to keep the health care institution financially viable? Hospitals have closed their doors because of financial losses, and many hospitals, especially in inner-city areas, are on the verge of bankruptcy.

Some prepaid health maintenance organizations (HMOs) use "gatekeepers" to keep patients in need of emergency medical care away from immediate assistance at institutions other than the HMO parent hospital. Moreover, the HMO's income may depend on *not* hospitalizing patients, *not* using ancillary tests, and *not* permitting ED visits. Nevertheless, it is prudent and ethical for EPs to err on the side of providing for the patient's needs.

Morality of Triage Decisions

In the aftermath of a massive natural or man-made disaster, triage officers face difficult decisions about who will receive scarce lifesaving treatment and who will be left to die without treatment. Even in "routine" ED triage, decisions about who should receive treatment priority and who can wait for treatment may, at least occasionally, have life-and-death consequences.[89,90]

Triage provides a method to distribute health care resources when patient needs exceed available resources. Triage operates along a continuum of decreasing resources, social order, and the resource-to-patient ratio. Arrival patterns, triage methods, and the applicable ethical basis for triage vary along this continuum.

Most triage systems are designed to serve the values of human life, human health, efficient use of resources, and fairness. Nevertheless, because of the variety of specific triage settings and goals, no single "correct" way to perform or to justify triage can be identified. Routine triage in the relatively resource-rich setting of the modern hospital ED, for example, focuses appropriately on maximizing benefits for each individual patient, giving treatment priority to patients whose needs are most urgent. In triage after a massive disaster, when not all individual needs for lifesaving care can be met, the focus may shift from an individual to a group perspective, and triage officers may seek to save as many lives as possible with the limited resources at their disposal. In special circumstances, such as times of war, military commanders may direct that triage systems devote scarce medical resources to achieve a nonmedical goal, namely, military victory. In situations of complete devastation, the lack of social order and minimal resources may make triage impossible.

Whether the choice of a triage system is justifiable will depend on an evaluation of the specific system itself, its underlying values and principles, and the setting in which it is applied.

Physician Response to Risky Situations

Over the millennia, personal values have dictated whether a physician would remain with his or her patients during extreme or catastrophic circumstances.[91] Physicians, even legends of medicine such as Galen, often fled to save their own lives. In the era of modern epidemics of unknown virulence and etiology, it remains a personal moral decision, especially for EPs who are on the frontline of these medical assaults.

How will physicians respond when a catastrophe involving personal risk strikes? The moral backbone of medical professionals may be tested as health care providers weigh multiple factors to

www.ketabpezeshki.com 66485457-66963820

determine whether to stay and carry out their professional roles or to step back and decrease their personal risk.

With incomplete information, providers may make decisions on the basis of heated emotions and panic rather than an accurate perception of risk. The decision to stay or to leave will ultimately depend on the individual practitioner's risk assessment and value system. Professional ethical statements about expected conduct establish important professional standards and norms, but each practitioner will interpret and apply them on the basis of his or her own situation and values. Recent historical precedent suggests that many physicians and other health care providers will dutifully care for the sick and needy, even at great risk to themselves. Although some EPs have worked in dangerous situations, most have not; nothing in day-to-day EM practice prepares EPs for the great opportunities and challenges that accompany a pandemic. EPs can, however, reflect on their professional and personal responsibilities in crisis situations, and public and private institutions can create plans for effective communication and care when a disaster strikes. If this can be achieved before the next pandemic or disaster that includes personal risk to clinicians, EPs, who are inevitably among those at highest risk, can be encouraged to "stay and fight."

"Proactive Ethics": How Can Emergency Physicians Change the Rules?

In every medical system, practitioners find that they repeatedly face identical ethical dilemmas. The normal outcome is an incomplete and often unsatisfactory solution made by administrators, lawyers, bioethics committees, or others. "Proactive ethics" involves changing the rules under which we operate. Easier done in some settings than in others, the process requires that all "stakeholders," those with a vested interest in an equitable solution, first come to the table and reach a compromise. Such groups often will include physicians, nurses, EMS personnel, lawyers, religious authorities, and representatives of affected groups (e.g., an organization of elders in the case of issues involving the aged). Armed with this agreement or even sample legislation that they can present to politicians, it becomes easier to change laws or administrative rules to address recurrent ethical dilemmas. One such process led to a landmark out-of-hospital advance directive law, which markedly lessened unwanted EMS resuscitation attempts.[42] It also led to an extensive statutory surrogate list and a simplified set of advance directives. Proactive ethics lies in the role of public policy—an arena in which EPs are well suited to play a pivotal role.

C. Palliative Care in the Emergency Department

D. Special Situations and Diseases

KEY CONCEPTS

- In emergency medicine, it is essential to act rapidly, with the presumption of curative goals, and it may be impossible to withhold initial interventions.
- Advance directives and patient wishes should be honored whenever possible, including withdrawal of invasive support if the patient's desire to not receive such treatments is determined after initial emergency department (ED) intervention.
- When the patient cannot speak for himself or herself, the physician needs to search for the correct proxy according to patient wishes and state law, when there is time to do this.
- Suffering is not the same as physical pain: The body experiences pain, whereas persons experience suffering, particularly when physical changes threaten their future.
- Patients have individual perceptions of burdens and benefits when they live with chronic illnesses. The only way to understand a person's quality of life and whether treatment is "right" for a patient is to have a conversation to explore his or her wishes and values.
- An important aspect of the initial ED evaluation of a patient with a life-limiting illness is to ascertain the patient's general wishes regarding future resuscitation and treatments. The conversation with the family and patient can begin with the following questions: "What kind of resuscitation do you wish to receive if an emergency occurs after admission?" "Whom do you want to make decisions for you if you cannot?"
- A discussion of goals of care is more effective if it starts by clarifying the patient's broad values and goals. From the broad discussion, the clinician can suggest what procedures may or may not be useful in attaining the patient's goals.
- The purposes of hospitalization for persons with severe terminal diseases should be clear and in line with the patient's values.

End of Life

Jean T. Abbott and Susan Stone

PERSPECTIVE

The emergency department (ED) frequently is the site of critical turns in people's health. It is the place where sudden, unexpected deaths occur and bad news must be delivered to survivors. The ED also is increasingly a source of care for patients struggling with chronic diseases, persons in the late stages of life-limiting illness, and people actively dying. Many of these patients are elders with advanced disease and require discussions about withholding or withdrawal of life support in the ED.[1] Palliative care is the medical specialty that is focused on end-of-life care, and some of its principles are being incorporated into the Model of the Clinical Practice of Emergency Medicine.[2] The integration of quality management of the dying patient into emergency medicine practice presents challenges but also incorporates communication and negotiation skills that can be used by emergency physicians in many aspects of their practice.[3]

Death in the ED differs from death in other areas of the hospital in several ways: deaths often are unexpected; the patient and family and their values often are unknown to ED staff; trust needs be established rapidly; and management decisions often must be based on limited medical information. These factors contribute to stress for the emergency care team in managing the first few minutes of a critical illness. The initial response to life-threatening presentations in the ED must be to treat aggressively and to resuscitate persons in extremis in the absence of knowledge that this is counter to the patient's wishes. Much of the core of emergency medicine is devoted to prevention of untimely death in people with severe trauma, a "heart too young to die," or another sudden, unexpected life threat. However, when resuscitative and rescue efforts fail, when a patient's wishes to forgo further interventions become clear, or when the natural end to life comes, the emergency specialist should be prepared to withdraw unwanted treatments, to make the patient comfortable, and to lead the staff and the patient's loved ones in giving the patient's death the meaning and respect it deserves.

PRINCIPLES OF DISEASE

Epidemiology of Death and Dying

One hundred years ago, the predominant pattern of dying was a rapid, precipitous death from infectious diseases and accidents. With modern medical advances, chronic diseases have become part of the last years of life for most people. Three diseases—heart disease, cancer, and stroke—accounted for 60% of deaths in the United States in 2000, whereas unintentional injury accounted for only 4% of deaths.[4] Most people live with some limitation in their ability for self-care for 2 to 4 years before they die. Four common trajectories of dying have been described (Fig. 1). Sudden death (due to cardiac arrest, trauma, or other sudden event) occurs in only 15% of people. The other trajectories are more common and occur with roughly equal frequency. The predictable decline in patients with "terminal illness" during 6 months or less provides the basis for the hospice concept of managing the dying process for patients with cancer and terminal AIDS. In cases of organ failure (e.g., chronic obstructive pulmonary disease [COPD], heart failure, renal failure, and other progressive serious medical diseases), gradual decline is punctuated by intermittent exacerbations (entry-reentry decline). The time of death for people with these progressive and ultimately fatal diseases is not very predictable, and it often happens unexpectedly during an acute deterioration. These patients frequently are treated for acute crises in the ED. The fourth trajectory of gradual decline, or "frailty," is associated with some form of dementia in 50% of affected persons and a lingering course that can extend for many years, stressing and wearing out caregivers and other support systems as decline in functional abilities progresses.[5]

Several end-of-life skills are important in the practice of emergency medicine. One of these is to determine rapidly, when possible, the patient's wishes for interventions at a time of crisis. Wishes may be transmitted through written advance directives or direct conversation with a patient or proxy about general values or specific management choices that should guide ED management. Invasive interventions may carry greater risk and less benefit near the end of life. The patient's choices may include spiritual, economic, and community factors that the clinician cannot know without clear, rapid communication and establishment of treatment goals.[6] The national Education in Palliative and End-of-Life Care for Emergency Medicine (EPEC-EM) curriculum has been designed to help clinicians prognosticate better, convey medical and technical choices, and discuss goals of care with patients and families at these critical turns.[2]

Patients and families need to understand prognosis to make decisions about what treatments they want and to plan priorities for their remaining life. Studies have shown that physicians may be overly optimistic about prognosis, particularly if they know the patient well.[7] Functional status is a strong indicator of a patient's prognosis, particularly in patients with terminal cancer, for which the dying trajectory tends to be most predictable. For other end-stage diseases, validated scales to predict survival are commonly used in palliative care assessments. In the ED setting, rapid assessment of the likely prognosis can be accomplished by eliciting information about the patient's ability to perform activities of daily living (i.e., "performance status"). When a patient is not able to spend time out of bed, has reduced appetite, and cannot dress or bathe without assistance, he or she is likely to be in the last months of life. Such a patient should be eligible for the Medicare

www.ketabpezeshki.com 66485457-66963820

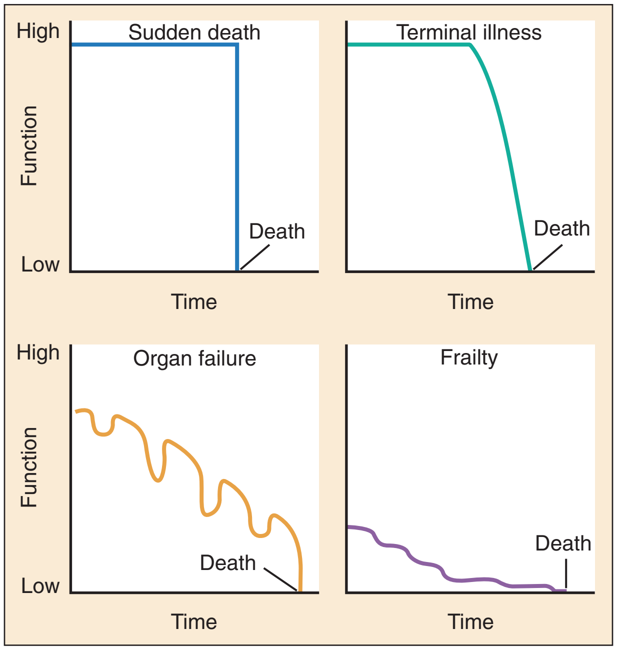

Figure 1. Theoretic trajectories of dying. (From Lunney JR, Lynn J, Hogan C: Profiles of older Medicare decedents. J Am Geriatr Soc 50:1108, 2002.)

hospice benefit. This is the time to involve hospice or palliative care consultants either in the ED or during hospital admission. If a patient has already enrolled in hospice, it is important to contact the relevant hospice program (accessible around-the-clock) from the ED before treatment and disposition decisions are made.[2,5,8]

In Western culture, death has become "medicalized" in the last 50 years.[9] Modern technology often allows human control over the timing, site, and pace of dying. About half of deaths in the United States occur in a hospital and another quarter in nursing homes.[10] Frequently, the dying process is accompanied by invasive diagnostics and medical interventions, even when death is expected and these interventions may increase suffering. Our society often sees death as the failure of scientific know-how rather than the natural end to a life. When death is approached with less fear by both patients and physicians, it is possible to help patients and families make the best of the time remaining to them and to accept death as natural.

Definitions of Death

Biologic definitions of death are currently the subject of considerable debate. Twenty years ago, cardiorespiratory failure defined death because this was rapidly followed by brain death (which could not be directly measured) caused by failure of oxygenation and perfusion. Death was a distinct biologic event because all vital systems stopped when one of them failed.

Currently, cardiopulmonary "death" is not necessarily inevitable or irreversible. Ventilation can be maintained externally, and even circulatory support through pharmacologic means or pump assist can sometimes buttress an inadequate heart. Because of this, a second pathway called "brain death" has been conceptualized. One impetus for development of a concept of brain death was the need to define a biologic and ethical boundary to life in the procurement of organs for transplantation. The brain-based determination of death is defined by the irreversible failure of clinical function of the whole brain, manifested by apnea, profound coma with unresponsiveness, and absence of brainstem reflexes.[11] The most common causes of brain death in adults are traumatic brain injury and subarachnoid hemorrhage. In children, the primary causes are accidental or nonaccidental trauma and asphyxia.[2,11] Although the emergencies causing eventual brain death often present first to the ED, the criteria and irreversibility standards are rarely met in the first hours after the resuscitative effort.

Declaration of brain death allows harvesting of organs while cardiopulmonary support and organ perfusion are continued and accounts for the majority of solid organ donations. A new protocol designed to increase the pool of organ donors and to acknowledge the rarity of complete brain death defines "non–heart-beating" organ donors. Such patients have a dismal prognosis for meaningful survival, but complete brain death will not occur until the time of cardiopulmonary arrest. Pulmonary and cardiac support is withdrawn, death is declared after an interval of several minutes, and organs can be harvested with a minimum of warm ischemia time. The issues surrounding society's definitions of death are complex, and the struggle to balance respect for persons and their bodies with the need for transplantable organs is expected to continue.[11-13]

It is important for physicians to be clear in their medical language relating to death. A patient is allowed to "die naturally" when the ventilator and cardiac support are removed. A patient who is declared "brain dead" is dead even though the person may appear to be alive, with pulse and chest rise, to the family.[11] "Whole brain" death requires failure of the brainstem as well as cortical function (i.e., coma). The confusion over medical definitions of death is made greater by cultural and religious variations in concepts of death. The different criteria also can lead to suspicion among the public that these definitions are malleable and serve physician agendas rather than respecting the patient.[11] In the ED, cardiopulmonary death is the only death that can be recognized, and the term *brain dead* is to be avoided because it requires time and strict criteria for diagnosis. However, the emergency physician has an important preparatory role in explaining the status of the patient who is breathing and who has a pulse (perhaps after a successful resuscitation effort) but may ultimately die a brain death. It is helpful to introduce the family to the concepts of prognosis and brain injury and the further steps that will occur in the succeeding hours that will give physicians and family a clearer picture of whether an injury or insult is fatal.

Related Issues

Futility

Physicians are not required to offer treatments that are not beneficial. Unfortunately, information available in the out-of-hospital setting or the ED often is insufficient for a judgment to be made that a particular patient's condition is "terminal" or that treatment efforts would be "futile." In the United States at present, when cardiopulmonary arrest occurs, physicians proceed with full resuscitative measures unless there is a clear understanding that this is contrary to the patient's wishes. Although the term *futility* can be a nontechnical expression of a physician's assessment that a proposed intervention is nonbeneficial, the definition is hotly debated. Most recently, the term *futility* has also been conceptualized in two ways: goal futility (the goal of the proposed treatment plan is unlikely to be realized) and value futility (the goal of treatment does not hold value for the patient). Unilateral physician judgments of futility are not appropriate in the emergent patient, although both aspects of futility can be useful in conversations with patients and families while discussing goals and options in the ED.[14]

Quality of Life and a "Good" Death

As technology gives physicians the ability to stabilize patients with serious and incurable diseases and to manipulate the timing of

www.ketabpezeshki.com 66485457-66963820

death, and as people increasingly exercise their autonomy to decide how and when their dying should occur, more conversations occur about what constitutes a "good death." There is evidence that the quality of life for persons who live into their 80s is better than it was 20 years ago.[15] For that, medicine can be proud. However, there are also serious deficiencies in end-of-life care. Whereas almost 95% of people express the wish to die at home, more than 70% die in an institution.[10] The patient's priorities are often marginalized, as they commonly include both medical and nonmedical concerns. Singer and associates suggested that five topics predominate in people who are dying: having pain and other symptoms adequately relieved, avoiding inappropriate prolongation of dying, achieving control, relieving others of the burden of their dying, and strengthening personal relationships.[16] The medical profession has not been quick to understand the broad scope of the patient's wishes and to honor them in planning and care.[17]

In the ED, resuscitation is performed unless the patient's wishes to the contrary are clearly known, even though the number of patients completing some form of advance directive before nontraumatic death is now about 70%.[18] Information that cardiopulmonary resuscitation (CPR), intubation, or other invasive treatments are not desired can be conveyed in the form of written advance directives, a state-authorized "no-CPR" or do-not-attempt-resuscitation (DNAR) directive, clear indications from the person assigned the patient's durable power of attorney for medical affairs, or communication with the patient's physician through the newer POLST (Physician Orders for Life-Sustaining Treatment) paradigm orders.[19] However, evidence of wishes from prior conversations between patients and family or physicians is rarely available in an emergency situation. Most people—both patients and surrogates—do not understand what "do everything" means, and surrogates are poor at predicting care that their loved one would want or not want. In one study comparing patient and surrogate choices about life support, surrogates guessed patient wishes only 68% of the time, little better than chance.[20]

In patients with severe disabilities, physicians and other health care providers likewise have a difficult time judging quality of life and the patient's wishes at the end of life. Gerhart and colleagues[21] surveyed emergency care providers' hypothetical attitudes toward quality of life after spinal cord injuries and compared their responses with those of high-level spinal cord injury survivors. Only 18% of providers (e.g., emergency medical technicians, nurses, and physicians) imagined they would be glad to be alive after a severe spinal cord injury, whereas 92% of survivors were glad to be alive. Eighty-six percent of the quadriplegics thought that their quality of life was average or better, whereas only 17% of emergency care providers predicted they would have a similar view of their quality of life as a quadriplegic. People's assessment of what is a "good life" changes with time, age, and the realities of illness.

Goals of Medicine

Medical authorities and philosophers have long debated the proper goals of medicine. Physicians are most familiar with the goal of "curing" disease. However, Ellen Fox reminds us of the complexity of our task in medicine: "Although cure is unquestionably an appropriate goal of medicine, other goals are important as well: promoting health, preventing illness and injury, restoring functional capacity, avoiding premature death, relieving suffering, and caring for those who cannot be cured."[22] In Western society, the curative model predominates, and physicians are rewarded for being analytic and rational. The disease, not the person, becomes the object of analysis. Symptoms are clues to diagnosis rather than problems to be treated in and of themselves. Fox points out that the palliative care emphasis on "relief of suffering, control of symptoms, and restoration of functional capacity" is really just one end of a spectrum of care that a physician provides to all patients. Even patients with life-limiting conditions often have reversible elements that physicians can address; likewise, even the patient with streptococcal pharyngitis wants symptom relief in addition to cure. So the goal of medicine may be to discern where to place the emphasis: the curative and the palliative models need to be balanced in varying proportions to optimize care for the individual patient.[22]

If the physician's goal is to relieve suffering, he or she must distinguish between *pain* and *suffering*. Eric Cassell first introduced the idea that a primary goal of medicine is the relief of suffering in a landmark article in the *New England Journal of Medicine* in 1982.[23] Cassell emphasizes that pain happens to bodies but that suffering happens to persons. Suffering derives from the meaning behind pain or other symptoms to that person. Suffering is "the state of severe distress associated with events that threaten the intactness of the person."[23] Patients may be in severe distress without any physical pain; others may experience their pain with very little distress. Patients suffer, as Cassell pointed out, "when they feel out of control, when the pain is overwhelming, when the source of the pain is unknown, when the meaning of the pain is dire, or when the pain is chronic."[23]

Palliative and Hospice Medicine

The World Health Organization defines *palliative care* as "an approach that improves quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual." Palliative care is usually provided by an interdisciplinary team of experts that offers comprehensive care and support systems for patients and their health care providers, both at the end of life and when they are undergoing treatment for advanced illness. Some patients near the end of life are being treated with curative intent (e.g., before transplantation) but are in palliative care. Palliative management is provided to inpatients through consultation; outpatient services are delivered at home, hospice, or long-term care facilities.[24] Examples of some acute palliative care interventions that can be applied in the ED setting are described at the end of this chapter.

Hospice care is the component of palliative care for patients who are likely to be within 6 months of death. The hospice movement, which started in England in the 1950s, initially sought to provide a haven of medical care for persons dying of cancer. Home and inpatient hospice programs now exist throughout the United States and are funded through Medicare. If a clinician would "not be surprised" if a patient died within 6 months if the disease ran its natural course, a hospice evaluation would be appropriate. The patient is "hospice eligible" if the hospice judges that the patient's lifespan is likely to be less than 6 months and Medicare will certify the patient for hospice. Currently, hospice care is provided for an expanded spectrum of end-stage illness, including cancer, organ failure (e.g., heart, liver, kidney), neurologic diseases, and terminal AIDS.[2,8]

Currently about 40% of patients die while receiving hospice services. Of these, about 40% are patients with cancer. The median time from enrollment to death is 21 days, often leaving insufficient time for many of the services that hospice can offer.[25] Although physicians may have difficulty quantifying a patient's likely lifespan as less than 6 months, prognostic tools exist, and enrollment criteria are based on lack of curative intent as well as progressive decline in function.[2,8]

The palliative care movement has developed as an expansion of end-of-life care to include not only hospice-eligible patients but

www.ketabpezeshki.com 66485457-66963820

also patients with incurable, debilitating chronic non-cancer illnesses (e.g., COPD, congestive heart failure) that require symptom control, often in addition to some disease-modifying interventions, but with a less clear time frame to death.[5] Consultation with palliative care specialists offers patients a mechanism to discuss and to review management of symptoms and medical interventions that patients desire or wish to avoid. Hospice referral can occur when this is desired and possible. Several studies demonstrate that palliative care management may extend life while saving money and increasing patient satisfaction.[26-28]

Emergency Medicine and End-of-Life Care

Emergency physicians encounter death more frequently than physicians in many other specialties do. Resuscitation and restoration to functional life will always be a primary goal of practice and research in our field. However, seriously ill patients treated in the ED often present with important but less emergent complaints, and the physician often does have time to explore options for care with patients or family. Even when a patient has a severe chronic disease that is not curable, interventions are available that can improve the quality of life. On the other hand, at the end of the course of chronic disease, death is not always unwelcome.

Addressing the needs of patients and their families in the ED at these critical times requires an important set of skills. In 2006 the American Board of Emergency Medicine joined with nine other specialty boards to cosponsor the American Board of Hospice and Palliative Medicine. This alliance has recognized the real need of emergency physicians to participate in addressing the wide range of interventions and management decisions that are pertinent to the end of life. The integration of emergency medicine and palliative medicine has stimulated educational efforts to define the scope of ED-based palliative care and curriculum design.[2,29] The rest of this chapter is devoted to out-of-hospital end-of-life concerns and to the aspects of end-of-life care that should be part of every emergency physician's skill set: delivering bad news, death notification, establishing and honoring the patient's goals of care and advance directives, symptom control, and palliation.

SPECIFIC DISORDERS AND CONCERNS

Out-of-Hospital Considerations

Historically, out-of-hospital systems were designed to provide immediate resuscitation, stabilization, and transport of seriously ill or injured persons to EDs. Aggressive and early resuscitation, through CPR, airway management, defibrillation, fluid resuscitation, and trauma stabilization, has resulted in significant benefits and reduced mortality in patients with critical illness or injury for whom survival is time dependent.

However, emergency medical service (EMS) systems also are called to transport patients who have died or to assist patients who are in extremis but whose death is expected. As well, EMS is activated for patients with acute decompensation of chronic medical conditions, such as heart failure or COPD, and for acute symptoms that occur in the context of terminal conditions when caregivers at the scene cannot cope. Patients at the end of life may desire aggressive interventions for acute exacerbations of chronic illnesses, or they may prefer only supportive care or transportation to avoid unwanted interventions. In emergency situations, it may not be possible to determine the patient's underlying medical conditions or wishes. In some situations, a titrated response is possible, and noninvasive supportive care (such as positioning, suctioning, oxygen, or mask ventilation) during transport can buy time until the ED can further assess and clarify the patient's goals of care. However, patients in the last 6 months of life increasingly have physician orders documenting their wishes (POLST and others), and EMS providers need to ask for and honor these.[19]

Field Death Pronouncement

Several physiologic circumstances have been identified in which out-of-hospital providers should not initiate or continue CPR because of uniformly poor outcomes and no benefit from intervention. American College of Emergency Physicians (ACEP) and American Heart Association (AHA) guidelines state that CPR should not be initiated in patients with nontraumatic cardiac arrest and signs of irreversible death, such as decapitation, dependent lividity, or rigor mortis.[30,31] ACEP policy recommends discontinuation of resuscitation in the out-of-hospital setting if the patient remains in asystole or wide-complex pulseless bradycardia after a trial of adequate resuscitation, including CPR, intubation, medications, defibrillation, and pacing.[30] The National Association of EMS Physicians supports this approach. Termination of resuscitation efforts in nontraumatic cardiac arrest patients should be made in agreement with online medical direction and predicated on access to witnesses or family, provider comfort with death notification and grief counseling, and safety and logistical considerations.[32] In some systems, newer physiology-based algorithms for termination of resuscitation are being developed.[33] If questions arise about resuscitation, CPR and advanced cardiac life support measures should be initiated and the patient transported. It can be easier and ethically more sound to withdraw care in the ED than to withhold care at the scene.[2,34]

Honoring Advance Directives to Withhold Resuscitation

Honoring of patients' wishes at the end of life should be a goal for both out-of-hospital and ED personnel. Out-of-hospital providers need to be aware of the standards for honoring DNAR requests in their respective states.[31,32] In addition, providers need to be knowledgeable about types of advance directives and the surrogate laws for the state in which they practice. In most EMS systems, field pronouncement of death requires physician base-station consultation. The problem of unwanted resuscitation remains. In one survey, 98% of providers had questioned whether specific life support interventions were appropriate for patients who appeared to have terminal disease.[35] In another study, 6% of cardiac arrest calls were for people with DNAR orders.[36] Unilateral EMS provider judgment to forgo resuscitation has been reported, but snap judgments that patients are "terminal" are not necessarily accurate and should not be the sole criterion for withholding of interventions.[37] Barriers to implementation of prehospital protocols to terminate resuscitation include pay structure for EMS services, legislative mandates, and cultural norms in local communities.[38]

The identification of valid directives to withhold CPR or intubation is a problem for out-of-hospital providers. Information about patients' wishes and underlying diseases is frequently confusing, DNAR requests may be difficult to validate, and rapid intervention is frequently required. The ACEP recognizes the difficulties in respecting patients' desires to forgo resuscitative efforts and has issued guidelines for development of out-of-hospital DNAR policies.[30] In some states, statutory authority for EMS personnel to honor DNAR orders has been developed, but provisions vary widely. Written statements or identification bracelets must be consistent, easily recognizable, legally acceptable in that state, and clear about what resuscitative measures the patient would and would not wish to receive.[30,32] Likewise, a family member or friend who is present at the scene and has valid medical durable power of attorney for health care documentation may make decisions to initiate or to refuse treatment measures on behalf of the patient. The most widespread initiative to provide out-of-hospital written

www.ketabpezeshki.com 66485457-66963820

directives to limit life-sustaining care is the Physician Orders for Life-Sustaining Treatment (POLST) paradigm program, which started in Oregon and provides EMS and other providers in all settings with an order set clarifying patients' wishes near the end of life. This program is being adopted in other states.[19]

Several concerns about the validity of written advance directives persist: the patient's wishes can change over time, nonstandard forms of DNAR requests (such as "medical alert" bracelets, notes on prescription pads, or tattoos) cannot be recognized, and there is a theoretic concern that relatives or bystanders may not be accurately relaying the wishes of the patient.[37] Most out-of-hospital providers think that end-of-life skills are important; 93% of Oregon EMS providers found POLST orders helpful in the event of a prehospital cardiac arrest, and two thirds thought they were useful in patients who were not in arrest.[39] Significant gaps in training and knowledge about end-of-life training have been recognized by paramedics.[35]

Honoring Verbal Requests to Withhold Interventions in the Field

In most EMS systems, verbal requests to limit resuscitation are not accepted because of the concern that out-of-hospital providers cannot confirm that these represent the patient's current wishes. In view of the significant incidence of "unwanted" resuscitation, King County in Washington State has introduced a new protocol of allowing emergency medical technicians and paramedics to withhold resuscitation in situations in which family or caregivers indicate that no resuscitation is desired and the patient has a terminal condition (i.e., death is expected and the patient is under a physician's care). EMS personnel do not need direct physician approval to forgo resuscitation. The incidence of non-initiation of resuscitation increased from 5.9% to 11.8% in EMS services adopting the expanded standards.[40] Before implementing a similar protocol, Los Angeles County reviewed run sheets and found that 6% of cardiac arrest patients had a written DNAR order, but 10 of 55 patients were resuscitated because paperwork was not available. A family member or medical history was available at the scene for more than half of almost 900 nontraumatic cardiac arrest patients, indicating a potential to forgo resuscitation in a significant number of patients.[36] A liberalization of protocols should be accompanied by population buy-in and legal protections against errors because wrongful death suits remain a theoretic concern. EMS provider comfort level with expanded standards for non-initiation of resuscitation has been high.[37,40]

Supportive Out-of-Hospital Treatments near the End of Life

Patients at the end of life can benefit from supportive or palliative treatments at the scene and during transport. Positioning, suctioning, and administration of pain medication and oxygen for dyspnea may be important to increase the patient's comfort. Before an intravenous line is established, EMS personnel should ask the patient's permission to do so because even the pain associated with insertion of the line may be counter to a terminal patient's wishes. If the patient is being transferred from a long-term care facility to the ED, all care instructions, CPR directives, advance directives, and contact names and numbers need to be transported with the patient; these will be helpful in guiding continuing care in the ED.

Management of Hospice Patients

Although hospice care protocols are written to avoid activation of the EMS system unnecessarily, scenarios routinely arise in which the patient is in the dying process and help is needed. Unexpected medical deterioration, concern for the patient's perceived or real suffering, or a feeling of helplessness can and should trigger calls to 911. Family members may be unable to handle new symptoms or may disagree about the best way to help the dying person. Although some families may request death pronouncement at home, out-of-hospital providers should involve medical control. Transport with comfort care should be offered if the family wishes help or if the setting appears uncomfortable for those involved.

Suicide

Although respect for the patient's wishes is a core value in today's society, suicidal patients frequently are impaired and have doubtful decisional capacity.[41] Modern medicine assumes that suicidal depression usually is treatable. Patients near death from suicide should receive full resuscitative efforts unless there is a specific exception, such as physician-assisted suicide in Oregon and Washington, with formal documentation and an alternative protocol for out-of-hospital providers to follow.[42] If the patient is dead and meets criteria for resuscitation not to be started, the coroner or medical examiner should be notified. The scene needs to be protected to allow an investigation, if needed, because the history is rarely clear or complete during the emergency call. Decisions should be made after consultation with the medical control physician.

Death in the Emergency Department

Delivering Bad News

Every emergency physician will be required to communicate bad news to patients, family members, and caregivers. The manner in which this is done may make a difference in the course of subsequent grief and coping.[43] Compassionate communication can strengthen trust and foster collaboration in planning between the medical team and the patient and family. Emergency physicians have particular challenges in delivering bad news. They do not have ongoing relationships with their patients, and the bad news may be abrupt and unexpected. However, sometimes the lack of a prior relationship allows a more frank and open conversation about a patient's illness, prognosis, and wishes, particularly when the patient has a severe chronic disease.[44]

The goal of skillfully breaking bad news is to reduce the severity and the duration of stress and encourage engagement of coping mechanisms, both for physicians and for patients and their caregivers. According to a theoretic construct proposed by Ptacek and Eberhardt, staff and physician stress often peaks just before transmission of the bad news, whereas patient or caregiver stress emerges after delivery of the bad news.[45] Physician stress correlates directly with the severity of the news as well as with any responsibility for the outcome that the medical team may feel and inversely with the amount of experience in delivering bad news. Many providers feel inadequately prepared for death disclosure or delivery of bad news about a new diagnosis or turn in health status for a patient with a life-limiting illness.[46,47] Skilled resuscitation, diagnosis, and treatment of patients are key to management of the external sources of provider stress. Anticipatory stress of delivering bad news may be reduced by use of a structured protocol, with practice, and by being intentional about the physical and social aspects of the setting.[45] Experience with revealing medical error or other aspects of responsibility for outcomes has not been well studied.[48]

Several initiatives to improve delivery of bad news have been introduced. These encourage training in communication skills, explicit instructional sessions, role playing, use of standardized patients, and observation of colleagues who are comfortable with this aspect of patient care.[48-51] Little research has examined the best

Box 1 Delivering Bad News

The steps listed can help you think critically about how best to communicate at a time when stress is high. See the text for details about each step.
Step 1: Physician preparation
Step 2: What does the patient know?
Step 3: How much does the patient want to know?
Step 4: Sharing the information
Step 5: Responding to feelings
Step 6: Planning and follow-up

Modified from Buckman R: How to Break Bad News: A Guide for Health Care Professions. Baltimore, Johns Hopkins University Press, 1992.

methods of increasing patient and family satisfaction with this important aspect of patient care.[47] If the physician develops patterns to insulate himself or herself from stress, stress may increase for the receiver, whose needs should be primary; physicians should avoid use of vague language, delegation to others, or delaying or rapidly disengaging from the encounter.[44,45]

For the patient and family, the ED typically is the place where bad news is sudden and unexpected. This can certainly make the strain even more severe and overwhelming. Trust between ED caregivers and critically ill patients or their survivors, who were unlinked strangers just a few minutes before, does not come easily. Whereas providers may focus on the content of the information they should convey, patients focus more on the process.[43] Surveys of patients and families have identified the following factors as desirable for receiving bad news: privacy when receiving news, ability to express emotions safely, information that is free of unclear language or medical jargon, empathic and caring attitude, allowance for hope, and ability to ask for and receive good medical information.[45,49] One proposal for encouraging provider empathy is to structure a conversation according to the NURSE pneumonic: the provider *n*ames the emotions observed; confirms whether this *u*nderstanding of the receivers' feelings is correct; expresses verbal and nonverbal *r*espect for the receivers' feelings; *s*upports them through expressions of concern, understanding, and willingness to help; and *e*xplores additional concerns.[44]

The steps listed in Box 1 and explained in detail in the following paragraphs are designed to shape the interaction to facilitate the patient's or survivors' work through this stress and movement toward coping. This six-step template was adapted from Buckman's work and adopted also by the Education for Palliative and End-of-Life Care (EPEC) teaching project.[2,44,52] Key to moving through the process of delivering bad news is the "ask-tell-ask" interactional framework in which the physician is guided by the patient and family in regard to the pace, amount of information, and style that will work best to let them feel and hear what they need.[44]

Step 1: Physician Preparation

Before the physician interacts with the family or patient, preparatory steps are important. These include confirming all medical facts of the case, clarifying the name of the patient, being aware of any uncertainty about the patient's identity, and knowing the relationships between the patient and those with whom one will be talking. The physical site for the conversation should be quiet and allow private exchange of information and safe expression of emotions. This is sometimes difficult in the ED, but a family room or other quiet area usually is available. If the patient can be included, moving the patient to a private area is helpful, or key members of the patient's support group can be gathered around the bedside.

Physicians should identify themselves and their position, directly address the patient (when present) or the key persons receiving the news, and refer to the patient by name. Before beginning the discussion, the physician should sit down close to the patient, make direct eye contact with the patient (or close relatives), and be physically and mentally open to their concerns and needs.

Step 2: What Does the Patient Know?

It is useful to know what the patient or family understands before the delivery of news. An introductory question can be used, such as, What do you understand about your illness? or What have you been told happened to [name of spouse, sibling, other]? This information helps the physician to see the event as the patient and family are seeing it and to adjust the mode of delivering this news to their understanding. When patients and families may expect "the worst," this tactic can be perceived as delaying. In a less critical situation, however, asking about previous testing, conversations with physicians, and understanding of the patient's illness can help the subsequently delivered information fit into the patient's perspective and expectations.

Step 3: How Much Does the Patient Want to Know?

Every patient has the right to accept or to refuse medical treatments on the basis of informed consent. This also is true for information. Most patients appreciate the direct, simple truth about their condition and prognosis. There will, however, be some patients who do not want to receive the information themselves. These patients may wish to designate a friend or family member to represent them. This choice should be respected, if possible. People process information and make decisions in many different ways on the basis of their own cultural and religious views and previous experiences, and the Western principles of truth-telling and individual decision-making may be of lower priority to some families and communities.[44]

Sometimes the family learns of a diagnosis and prognosis before the patient does and requests that the patient not be told. The physician's alliance with both patient and family is important, although responsibility to the patient is primary. Physicians should explore why families do not want the patient told bad news: Is it a cultural tradition? Are they afraid of what harm it will cause the patient? Have they had previous bad experiences? The physician is still required to ask the patient how much he or she would like to know. Sometimes it is helpful for the physician to invite family members to be present for this discussion. Important information should be shared with the use of an independent interpreter (rather than a family member) if the patient does not speak the same language as the physician.

Step 4: Sharing the Information

In general, patients and families want to know bad news in a timely fashion.[45] This is sometimes uncomfortable, particularly when information is incomplete—a common occurrence in the ED. At the very least, it is recommended that patients and family be given a preparatory warning after introductions, such as, "I am afraid I have some bad news." In delivering the information, it is important to use simple nonmedical language and to make sure that the patient comprehends the information. Allow space for patients and family to absorb the news, to react, and to begin to ask questions. The patient and family stress response will lag behind that of the physician because the physician has had at least a few minutes to adjust to the current situation, but the family has not.[45]

Use of the phrase "I'm sorry" can be a reflection of empathy, but to avoid the implication that errors have occurred in treatment, some physicians have suggested use of expressions such as "I wish things were different" instead.[53] Survival data can sometimes be helpful, even when tentative. The physician's message should include some realistic hope and also reassurance that the

www.ketabpezeshki.com 66485457-66963820

patient will not be abandoned by the medical care team, even when cure or survival is unlikely.[49]

Step 5: Responding to Feelings

The reaction to bad news often is unpredictable and can range from sadness to overt anger. It is important for clinicians to be aware of the wide varieties of responses that will be seen. The patient and family should be allowed to express their feelings, even if this is uncomfortable. Acute grief is painful but important. The emergency physician should be prepared for both persons who turn inward and those who rage outwardly. Practicing and reflecting on these situations will allow the physician to deliver bad news and to support the survivors. In the ED, it is often helpful to invite members of the team into this meeting (e.g., social worker, nurse, or chaplain) who will not be pulled away to other care needs, can provide emotional support, and can help the family navigate through the early stages of grief as well as the necessary technical details.

Step 6: Planning and Follow-up

The ED is an entry point into the hospital if the patient survives. Family members should be encouraged to stay with the patient, particularly if it is possible that the end of life is near. Prognosticating may be difficult, in view of the limited information that can be obtained in the initial assessment. When initial management has stabilized a patient with an acute, critical turn, it may be appropriate to look ahead to decompensation that could occur later in the hospitalization. Some experts have suggested a "hope for the best and prepare for the worst" framework for conversation.[54] The physician can share the success, however transient, of any ED interventions and the positive news and hope that this provides. At the same time, he or she can prepare the patient or family for the possibility of later setbacks and have them consider what actions may or may not be appropriate if "the worst" happens.[6] If the patient does not have written advance directives, the emergency physician can facilitate the conversation, initiate written wishes, or at least advise the patient that the admitting physician will need to have an early conversation about future plans and goals for the patient. The physician should assure the patient and family of what the next steps will be, including hospital admission or discharge from the ED, consultation with specialists, support group referral, or chaplain services. It is important to make sure that the patient and family do not feel abandoned. When dying is near, active care and comfort are important medical tasks for the care team.

Death Notification

One particularly difficult form of "bad news" is death notification. Practice can help clinicians perform this task more smoothly (Box 2). In general, the format can follow the guidelines for delivery of bad news from Box 1. With death notification, however, diagnosis is certain, and specific actions will be required. Families do not have time to adjust or to think about options, and the news cannot be softened.

Death notification usually occurs after an unsuccessful resuscitation attempt. Physicians should be sure that they are presentable and wear a name badge. If possible, ascertain beforehand the names of the persons who will receive the notification, their relation to the patient, and what they know about the patient's condition. Other members of the medical team may have met them already and can be a source of background information. Sometimes the family initiated the 911 call and recognized that their loved one had died at that time. On the other hand, a family summoned to the ED may have absolutely no idea that they are about to be informed that their loved one has been critically injured or has died. For this reason, it is useful to have a nurse or colleague advise the family briefly about the general nature of the event and the status of resuscitation as soon as possible. When giving the news, physicians should use clear "dead" or "died" language to be sure that there are no misunderstandings about the outcome being conveyed. Those at the scene should be assured, if at all possible, that their responses to the emergency were appropriate, that the medical care team did all that was possible, and that the victim did not experience unnecessary discomfort. It is important to express appreciation for their presence in the ED or during the resuscitation attempts.

Box 2 Elements of an Empathic Death Disclosure

Introduce self/role.
Sit down.
Assume comfortable communication distance.
Use acceptable tone/rate of speech.
Make eye contact.
Maintain open posture.
Give advance warning of bad news.
Deliver news of death clearly (use dead/died).
Tolerate survivor's reaction.
Explain medical attempts to "save" patient.
Use no medical jargon; use language that is clear and easily understood.
Offer viewing of deceased.
Offer to be available to survivor.
Conclude appropriately.

From Quest TE, et al: The use of standardized patients within a procedural competency model to teach death disclosure. Acad Emerg Med 9:1326, 2002.

Phone Notification

If the first contact with survivors of an ED death is by telephone, it is recommended that the survivor be told to come to the ED if at all possible.[55] Although family members may ask or even demand to know if death has occurred, allowing some time for assimilation of news by delaying information about the final outcome may be more helpful for the grieving process.[56] Nonphysician staff may be useful to summon survivors and can inform the relative that the patient has been involved in an accident or is seriously ill and that things are not going well.

When the notification is to somebody who is more than an hour away or otherwise unable to physically come to the ED to receive the bad news, it often must be given by phone. The physician should make sure that the relative has someone present in the room if possible, ask the relative to be seated, and name the person involved. It is best to start with brief information about the circumstances and provide a warning that bad news is coming before breaking it. Even a few seconds of preparation in these circumstances can serve to partially attenuate the acute psychic pain. As indicated by the perceived response, the physician may need to ask, "Are you able to talk for a few minutes?" Some individuals may be unwilling or unable to continue after they hear the initial news, and they should be given an "out," but a definite time to reconnect should be established (e.g., 10 to 15 minutes).[55,56] Long-distance loved ones cannot view the body to facilitate confirmation and acceptance and inevitably have questions not addressed in the initial conversation. The relative should be given a telephone contact of someone who actually provided care for the patient. Otherwise, if a relative calls back, a lack of information about what transpired on a prior shift may cause frustration or even feed the person's denial or false hope that this tragedy has not happened.

www.ketabpezeshki.com 66485457-66963820

Viewing of the Body

At some time immediately after death, the family should be offered an opportunity to view the body. This may be the first exposure to the body for the survivors and can make an abstract and unreal notification more concrete. Although a majority of survivors find viewing of the body helpful, no attempt should be made to force this on survivors, and a few are not comforted by seeing the deceased.

If possible, the body should be moved to a small room, preferably away from the main treatment area. This not only ensures privacy but also makes the family feel more at ease. Family members should be warned of what to expect, such as color and temperature changes, injuries or invasive premortem procedures, and the presence of endotracheal and intravenous tubing. With sufficient preparation, most people are not shocked by the deceased person's appearance.

A staff member should remain in the room or within close range at all times. This contact allows the staff to help make the viewing an important and supportive aspect of the grieving process. At times, it may be necessary to touch the body to assure the family that this is appropriate. Survivors should be allowed to remain with the body for as long as seems appropriate. When gross disfigurement has occurred, the viewers should be warned about this, and the body should be discreetly covered when possible. Survivors may even find that helping to clean and prepare the body (particularly with a pediatric death), holding a loved one, or preparing for transport may allow a final expression of caring.

Family Presence during Resuscitation

It is increasingly common to invite a close family member to attend resuscitation attempts. Offering of this option has been endorsed in the 2005 AHA Emergency Cardiac Care guidelines[31] and by the EPEC curriculum.[2] Emerging evidence suggests that presence during procedures and resuscitations may be beneficial to surviving patients and family members who choose to stay and are not harmed. Less consensus exists among providers, and they often express discomfort with the concept. If resuscitation is to be witnessed by a family member, a staff member who is dedicated to supporting that person should always be present.[57,58]

Sedation for Survivors

Requests for tranquilizers, sedatives, sleeping medications, or just "something for the nerves" are common. The grieving process is important and difficult work. Prescriptions for a light sedative for a few days may be appropriate but usually require direct evaluation of the survivor by the physician. The survivor needs to know that the psychic pain is to be expected and where to turn for help and support during this difficult time.[55]

Autopsy and Closure

The "event" of death notification should be concluded with a physician expression of condolences and concern for the survivors—all physicians can honestly express sadness at being the bearer of such life-changing news.[53] In many hospitals, chaplains or social workers or nurses are trained in informing the family about arrangements for the body, including notification of a mortician and interface with a coroner, which is not uncommon in ED deaths. If the ED practitioner desires an autopsy, this is an appropriate time to request permission. Autopsies not only are valuable in contributing to the advancement of knowledge, education, quality assurance, and public education but also can be indispensable in minimizing guilt and blame associated with the death of a loved one. In addition, findings of unknown disease may be important for family members if there is a genetic factor. Whereas organ procurement organization staff should secure formal consent for organ donation, the rate of organ donation is positively influenced by the physician's comfort in answering family questions about donation.[59]

Consent for Procedures on the Newly Dead

The use of the newly dead to teach procedural skills is currently being debated in the medical community. It is important to educate residents in procedural skills, and emergency physicians often need to review procedures that they perform very rarely. The newly dead have been a silent source of learning in the past. Although some evidence indicates that the public generally supports the practice, serious questions about respect for bodies and the need for informed consent also have been raised.[60] The American Medical Association policy affirms that consent should be obtained from survivors.[61] In emergency medicine, it has been argued that obtaining consent is not feasible: finding authorizing survivors is difficult, voluntary consent is questionable in a stressful situation of sudden death, and time pressures require early resumption of other ED activities. Some authorities have tried to distinguish between invasive procedures (e.g., thoracotomy, peritoneal lavage, venous cutdown) and minor or less invasive ones, such as intubation. The current ACEP position is ambiguous and reviews arguments on both sides of the debate.[62] Hospital policies often determine whether the newly deceased can be used for training purposes and the manner of consent that is needed. Many believe that the performance of involuntary, nontherapeutic invasive procedures, including those performed during CPR, is an ethically unacceptable departure from a standard of care that emphasizes the centrality of respect for the patient, the patient's well-being, and the requirement for informed consent.[60,63]

Grieving and Bereavement

Grief is defined as emotional pain induced by sorrow and loss. It is associated with a constellation of symptoms and behaviors that are influenced by cultural background, current and past personal stressors, and relationship of the survivor to the deceased. Survivors are often the "patients" toward whom the emergency physician needs to direct his or her expertise in the case of an ED death. Giving bad news and sharing in the beginnings of the grief response are among the most difficult situations physicians need to handle. Whereas grief reactions are most commonly associated with death events, they also occur with sudden downturns in health or news that changes a person's outlook on the future. *Bereavement* is the situation of having experienced the death of a significant person in a survivor's life.[64] It is important to understand the range of what can be expected acutely and to be able to identify those survivors at risk for complicated grief. Recognizing survivors at higher risk for complicated grief may trigger earlier referral and decrease the risk for development of major depression and other stress disorders.[43]

The initial response to any death, whether expected or unexpected, is acute psychic pain that is associated with shock, disbelief, numbness, and inability to process further information.[55] Some persons display anger, loud screaming, crying, and occasionally acute anxiety or syncope. Others experience a calm dissociation or no reaction. The medical team may also recognize other, more cognitive reactions, including denial, guilt, sadness, fear, shame, and anger. Reactions may vary with the cultural and personal backgrounds of the survivors. A wide range of expressions is normal and expected. There is no "right" way to grieve, although, in the ED, outward reactions are often perceived as problematic and disruptive. The goal of the emergency physician is to support survivors as much as they permit and to avoid taking personally

www.ketabpezeshki.com 66485457-66963820

the survivors' anger, resentment, and other outward emotional expressions, even if they are directed at ED staff.[55] It is important to accept that some survivors will leave the ED still in denial and not emoting; they may need and want to postpone their grieving until they have what they feel is a more comfortable setting.

A variety of delayed emotional and physical symptoms can emerge as the survivor assimilates the reality that death has occurred. Physical symptoms include fatigue, anorexia, palpitations, hyperventilation, restlessness, headache, irritability, and insomnia. Emotional symptoms, in addition to guilt, anger, depression, and denial, include difficulty in concentrating, lack of organization, fear, and preoccupation with the deceased. These grief responses are to be expected. Special memories can trigger the grief response after the initial grieving period, and the memory and emotional pain of the loss may last a lifetime. Symptoms of grief, including psychic pain, numbness, intrusive thoughts, and disorganization, continue to occur during the recovery of most survivors, gradually becoming attenuated but recurring during months or years without clear "stages."[64,65]

Risk factors for difficulty in navigating the work of grieving can sometimes be recognized, even in the ED. Such factors include the death of a child or long-term spouse, the social isolation of the survivor, and a dependent or conflicted relationship with the deceased.[55] The physician may be able to alert the survivor's primary physician or support staff, or even the at-risk survivor directly, that ongoing work may be required to see this grief to resolution.

Grief Reactions in Staff

The impact of death in emergency medicine is significant for the staff, including physicians. Patients who particularly trigger stress reactions among the staff include young people, victims of random and senseless violence, and those who may have caused an accident or injury. ED stress can be significant when the patient needs to receive care rapidly on the basis of scant knowledge, which other professionals can later second-guess. The ED clinician also carries a personal history that may include circumstances that make particular emergencies hit a raw nerve; colleagues may not be aware, for instance, of an alcoholic parent, a sibling who committed suicide, or a friend killed by a drunk driver.

Because of the sometimes overwhelming contact with death and dying in the ED, it is important to have mechanisms in place to help address staff grief responses. At morbidity and mortality conferences, some discussion should be allotted to ethical, sociologic, and emotional sequelae of the cases being presented. The morbidity and mortality analysis process itself helps "make sense" of difficult situations and is part of the grieving process for health care practitioners, but often it emphasizes technical issues and minimizes the very real emotional impact. Case conferences that include a full range of medical personnel, chaplains, and social workers are useful to articulate and to share sadness, anger toward patients, and other emotional and cognitive work required for healing. It is particularly important to offer this to staff after major community disasters. Although for some people denial is a positive coping mechanism, for others the opportunity to share and to express emotions is needed to begin to move forward and resume the work of caring for patients.[64]

Palliative Care in the Emergency Department

Providing quality palliative end-of-life care is important in the ED. Education in Palliative and End-of-Life Care for Emergency Medicine (EPEC-EM) is a curriculum specifically designed to provide clinicians with the information and skills to practice ED-based palliative care.[2] The evidence that we do not know what others want for themselves or family members at the time of critical illness is discussed in the first part of this chapter. In the case of a cardiopulmonary arrest or major trauma resuscitation, attempted interventions are indicated unless the emergency physician has clear instructions from the patient or surrogate to the contrary. In less critical situations, however, guidance about the goals and direction of ED care is needed, and management strategies should be "patient centered."[2,66] Although some would argue that it is time-consuming and unnecessary for emergency physicians to develop a nuanced approach to care of patients near the end of life, it is no longer appropriate to provide all patients with maximal medical treatment and to "let the admitting doctors sort out the other issues." Comfort and quality of life become higher priorities for many patients with severe chronic diseases like cancer, COPD, heart failure, renal insufficiency, and dementia. Some procedures that are normal to aggressive emergency care may not be appropriate in this important group of patients. On the other hand, palliative care is often balanced with life-prolonging care in the management of patient who face life-limiting illnesses.[3]

Establishing Goals of Care

The primary skill that emergency physicians require in managing patients near the end of life is the ability to communicate. In a true emergency, such conversations take a back seat to resuscitation interventions. In many patients, however, it is not imperative to treat before discussion or diagnosis. In the ED setting, several approaches can be helpful to establish what treatments patients want near the end of life.

Reviewing and Honoring Written Advance Directives

Written advance directives can help guide treatment decisions in the ED as well as during hospital admission. Although such documents often do not foresee the particular medical emergency that precipitates an ED visit, their existence indicates that a patient has considered how his or her future medical care should (or should not) look. Advance directives may indicate that aggressive lifesaving interventions are desired or that a patient is in the dying process and wants to be kept comfortable. People's wishes change over time, and written advance directive requests should be reconfirmed at the time of an acute crisis. The clinician should be well versed in the technicalities of the various forms of written legal advance directives that exist.[2]

Verbal Requests to Limit Treatments

Verbal requests to titrate or to limit procedures can be made by the patient or the patient's surrogate. The clinician should determine whether the patient has decision-making capacity or, if such capacity is lacking, who will be the spokesperson for the patient. Invasive tests and procedures may not be performed on patients without their consent. In emergency situations, physicians rely on the "emergency exception" to informed consent and act to preserve life or at least to buy time to consider options. Many situations in the ED, however, do not require immediate intervention, or they allow a less invasive alternative (such as mask ventilation for respiratory failure) while the patient's goals are discussed.

Initiating a Conversation on Goals of Care

Emergency physicians see many sick patients who do not have written advance directives but are stable enough to have meaningful conversations about their needs and goals, their perception of where they are in the course of their disease, whether they wish to cure an intercurrent problem, which symptoms require management, and how much effort they wish to have undertaken if resuscitation is needed to preserve their life. Patients with seemingly lethal conditions may be aggressively pursuing curative or at least disease-modifying options, whereas the burden of suffering other patients are experiencing may not be obvious until they are

Table 1 Representative Questions for Initiation of the Discussion about End-of-Life Issues

DOMAIN	REPRESENTATIVE QUESTIONS*
Goals	Given the severity of your illness, what is most important for you to achieve? How do you think about balancing quality of life with length of life in terms of your treatment? What are your most important hopes? What are your biggest fears?
Values	What makes life most worth living for you? Would there be any circumstances under which you would find life not worth living? What do you consider your quality of life to be like now? Have you seen or been with someone who had a particularly good death or particularly difficult death?
Advance directives	If with future progression of your illness you are not able to speak for yourself, who would be best able to represent your views and values? (health care proxy) Have you given any thought to what kinds of treatment you would want (and not want) if you become unable to speak for yourself in the future? (living will)
Do-not-attempt-resuscitation order	If you were to die suddenly, that is, if you stopped breathing or your heart stopped, we could try to revive you by using cardiopulmonary resuscitation (CPR). Are you familiar with CPR? Have you given thought as to whether you would want it? Given the severity of your illness, CPR would in all likelihood be ineffective. I would recommend that you choose not to have it but that we continue all potentially effective treatments. What do you think?
Palliative care: pain and other symptoms	Have you ever heard of hospice (palliative care)? What has been your experience with it? Tell me about your pain. Can you rate it on a scale of 1 to 10? What is your breathing like when you feel at your best? How about when you are having trouble?
Palliative care: "unfinished business"	If you were to die sooner rather than later, what would be left undone? How is your family handling your illness? What are their reactions? Has religion been an important part of your life? Are there any spiritual issues you are concerned about at this point?

From Quill JE: Initiating end-of-life discussions with seriously ill patients: Addressing the "elephant in the room." JAMA 284:2502, 2000.
*It is important to give the patient an opportunity to respond to each question. Follow-up questions and responses should be based on careful listening to the patient, with use of the patient's own words whenever possible.

asked specifically about their illness and wishes. With or without written advance directives, the physician needs to ask about the patient's wishes.

Questions that can be useful to initiate this conversation are listed in Table 1. Pulling up a chair, sitting with the patient and family, and spending a few minutes clarifying the patient's values and view of the present and of the future may make a big difference in facilitating a plan aligned with the patient's wishes and values.

It is useful to start the "goals of care" conversation with a global understanding of the patient's illness, values, fears, and expectations. Then the "procedures" part of the conversation flows naturally. One suggestion is to explore with questions, such as, What is it that you hope for, given your current condition? and What is it that you are most afraid of? The physician can propose to the

Box 3 Palliative Medical Treatment Options to Enhance Quality of Life

- Pain control
- Control of fluid and electrolyte imbalance
- Nausea, vomiting, and constipation management
- Radiation therapy for bone pain, cord compression, or hemorrhage from tumors
- Drainage tubes for malignant effusions or obstructions
- Treatment of intercurrent infections
- Management of incontinence
- Supplemental oxygen
- Anxiolytics, antidepressants, and appetite stimulants when appropriate

patient and family what treatments will be useful (or not) in the context of overall goals and values, listening for disagreement or affirmation from the patient and family and engaging in shared decision-making.[66] Antibiotics may be appropriate for an acute pneumonia, but they may not be indicated in a patient with advanced dementia who has been bedridden and unable to communicate for several years. Intubation will be acceptable to some patients with COPD, whereas others who have struggled on the ventilator before may not wish to experience that discomfort again. Intravenous hydration is useful to correct dehydration but may merely increase secretions in the patient who is actively dying. All of these interventions need to be considered in the context of caring for the patient and enabling patients to achieve their goals.

Initiating Advance Directives and DNAR Orders

The ED can be an important link in initiation of advance directives because it often is the patient's portal of access to the hospital.[67] Wrenn and Brody described a small series of patients for whom the emergency physician wrote DNAR orders on admission.[68] Balentine and colleagues described another series in which few negative responses were obtained from the families who were approached.[69] Both authors pointed out that fragmentation in health care may mean that previous wishes are not translated into hospitalized settings and that the ED may be the best place to establish or to renew documentation of the patient's wish to forgo resuscitation at the outset of the hospitalization.[6]

Treating Symptoms Requiring Palliation

When a patient is suffering from a disease that is not curable, he or she may still want a variety of medical interventions as part of care: antibiotics for intercurrent infections, drainage of effusions that cause shortness of breath, wound care for decubitus ulcers, decompression of bowel obstructions, and aggressive pain management. The most common reason that patients with end-stage illness seek emergency care is for control of intolerable symptoms such as nausea, vomiting, dyspnea, severe constipation or diarrhea, and pain (Box 3).[2,70]

The ED caregiver may encounter several unfamiliar principles when treating symptoms in persons near the end of life. One of the more "foreign" concepts to most emergency physicians is the treatment of symptoms without diagnosis of the underlying cause, even though this often is the appropriate option in palliative care. In addition, the prioritization of aggressive pain management may feel strange. On the one hand, physicians have concerns about "drugging" patients or overtreating them, although these are mostly unwarranted. On the other hand, worry about unintended consequences may lead to underdosing of medications, leaving patients without desired relief. Concerns about respiratory depression arise when opioids are used, even though the risk of respiratory depression is minimal when the dose is titrated to the patient's desired endpoint. The EPEC-EM curriculum and EPERC (End of

www.ketabpezeshki.com 66485457-66963820

Life/Palliative Education Resource Center) Fast Facts are excellent resources for learning about strategies that are unique to palliative care for patients.[2,71] The following "pearls" from those programs may be useful.

Pain

For patients presenting with acute pain or chronic pain of moderate intensity (rated 5/10 or above), opioid use is appropriate (see Chapter 3). A thorough medication history should be obtained to determine tolerance and dose adjustments that may be needed. Pain assessment is different for patients with chronic pain because they may not show the abnormal vital signs or outward expressions of discomfort commonly observed with acute pain. Patients with advanced illness and pain may be tolerant to opioids and require high doses to achieve comfort. This causes discomfort on the part of the provider. Patients suffering from malignant pain may need continuous infusions of opioids to obtain relief or rapid titration protocols as well as adjustment of chronic doses of analgesics in the ED.[2,71]

When it is available, palliative care consultation can be helpful for treatment of malignant pain. However, pain and palliative care consultation is not uniformly available, particularly during the evening and night hours. Therefore, emergency physicians should have the basic knowledge to treat severe pain. Rapid opioid dose escalation is the most important principle in patients with cancer receiving opioids. Doubling of the dose may be required until successful analgesia is reached.[72] With intravenous administration of morphine, serum levels will be maximal in 6 minutes, so patients need to be reassessed and redosed promptly. Providing stable analgesic effect is important, and this is done by providing a long-acting formulation (e.g., MS Contin), with an immediate-release short-acting agent for breakthrough pain. Side effects from opioids should be anticipated as well. Rising serum levels of opioids stimulate the chemotactic trigger zone, causing nausea. Educating the patient that nausea will subside within days is helpful. Minimizing fluctuations by use of long-acting agents whenever possible can limit this form of nausea. Constipation is a common effect of opioids, and tolerance will not develop. Prevention is far easier than treatment, and a stimulant laxative should be part of all narcotic prescriptions for malignant pain. The use of nonsteroidal anti-inflammatory drugs may be helpful in potentiating the effects of opiates in cancer patients. Recognizing neuropathic pain also is important because medications such as gabapentin may be used. It is important to clearly explain the proposed treatment plan to the patient and caregivers, to monitor the response to treatment and side effects, and to coordinate changes in treatment regimens with the primary care physician.[2,71,72]

Nausea and Vomiting

Nausea and vomiting arise from triggers in the gastrointestinal tract, cerebral cortex, vestibular apparatus, or chemoreceptor trigger zone in the fourth ventricle. The neurotransmitters involved include serotonin, dopamine, acetylcholine, and histamine. Successful treatment of nausea and vomiting involves selection of the drugs that will target the right receptors. In addition to usual antiemetics, dexamethasone, octreotide (which reduces secretions and may be useful in intestinal obstruction), and tetrahydrocannabinol may be important adjuncts for the control of nausea.[2,72]

Constipation

Constipation is multifactorial near the end of life; causes include decreased mobility, medications, mechanical obstruction, and dehydration. Stimulant laxatives and then osmotic laxatives should be tried in escalating doses, and combinations may be needed. Opioid-related constipation can be a major problem. Every attempt should be made to prevent rather than to treat constipation by anticipating the need for stimulant softener combinations when opioids should be used chronically. In cases of mechanical small bowel obstruction, medical management with clear liquids, loperamide, and octreotide results in resolution in a majority of patients.[2,71]

Anorexia and Cachexia

Anorexia and cachexia develop in patients with advanced diseases and may be more stressful for the family than for the patient. Esophageal infection should be considered. Parenteral nutrition does not necessarily reverse this when it is part of end-stage disease and does not affect life expectancy. Appetite stimulants are sometimes useful.[2] Cachectic patients are susceptible to pressure ulcers and skin breakdown that can occur from being placed on a backboard or hard stretcher in the ED.

Shortness of Breath

Shortness of breath also can be part of the last stages of airway disease or cancer involving the lungs. There are many causes, and several treatments may be helpful. Options include symptomatic treatment with oxygen (which may not work if central triggers are operating), anxiolytics, and low-dose opioids, which may decrease the sensation of breathlessness. Malignant effusions may require drainage. In the actively dying patient, morphine and atropine can be used to dry secretions, to slow breathing rates, and to decrease the work of breathing.[2,73]

Depression

Psychosocial distress is exceedingly common in patients suffering with incurable illness. Anxiety and depression have been found to have a negative impact on survival and to decrease quality of life. These issues are best addressed by the primary care provider. Emergency providers can provide empathy and support and recognize that these symptoms are not inevitable components of the dying process and therefore deserve attention.[2]

Special Situations and Diseases

Advanced Dementia

Alzheimer's dementia is a prolonged and relentless chronic disease with a course that can extend up to 20 years. With severe dementia, patients may be combative, incontinent, and unable to ambulate. In the terminal phases of the disease, they are bedridden, mute, and dysphagic and suffer from intercurrent infections.[74] In the demented patient, invasive procedures often require restraints and sedation, and the emotional burden to the patient is high. Even hospitalization, administration of intravenous fluids or antibiotics, and other common interventions are frightening to patients with dementia. As an example, percutaneous gastrostomy or a feeding tube does not prolong life in a patient with late dementia, and qualitative benefits are questionable because provision of artificial nutrition does not prevent aspiration, provide palliation, or improve function in a progressive severe disease like dementia.[75,76] For the emergency physician, the increased burden in combination with decreased benefit, even of the simplest procedures like administration of antibiotics, means that interventions should be thoughtfully chosen and discussed beforehand with surrogates when there is time to do so. Addressing concerns of caregivers also is particularly important in dealing with families of patients with dementia. Depression is common in caregivers; the burden of caring for patients can be severe, and grieving may occur before death as the person that they knew disappears in front of them.

Renal Failure

Dialysis has been a technical success in prolonging life for patients without kidney function. Because it is now so common, physicians

www.ketabpezeshki.com 66485457-66963820

do not realize that the annual mortality rate is about 20% for patients on dialysis and 35% for those older than 65 years.[77] Understanding that dialysis is a choice and not a mandatory intervention may be useful in discussing long-term choices with patients and their families in the ED. In the patient with dementia or cancer, electing not to treat renal failure is an option that should be offered to patients and families.[77]

Heart Failure and Chronic Obstructive Pulmonary Disease

Although the physiologic parameters of terminal heart failure and COPD are well described, death from these diseases is commonly unexpected and may occur as part of a sudden acute deterioration that is not remediable. As a consequence of the entry-reentry pattern of dying associated with congestive heart failure and COPD, many patients will not receive good palliative care until the last days of life. However, some guidelines are available to assist the provider in determining prognosis.[78,79]

On the other hand, if the patient presenting with acute decompensation becomes stabilized, the emergency physician may have a unique role by having the opportunity for a conversation concerning advance planning with the patient and family. The emergency physician can establish what kind of resuscitation measures should be performed if the patient suffers a cardiac or respiratory event in the hospital and who should make decisions on behalf of the patient if he or she should become incapacitated at some time during the admission. In patients with many types of chronic diseases of the entry-reentry type (see Fig. 1), the period after an emergency has resolved (even if temporary) often is the best time to establish what interventions would be appropriate if decompensation occurs again. In terminal stages, an undue focus on diagnostics is more common in these patients than in patients with cancer, particularly if the lethality of these conditions is not acknowledged. Palliative care or hospice referral often is useful in assisting patients with understanding and acknowledging of the prognosis and establishing intentional and realistic projects and goals for their remaining life.

KEY CONCEPTS

- In emergency medicine, it is essential to act rapidly, with the presumption of curative goals, and it may be impossible to withhold initial interventions.
- Advance directives and the patient's wishes should be honored whenever possible, including withdrawal of invasive support if the patient's desire to not receive such treatments is determined after initial ED intervention.
- When the patient cannot speak for himself or herself, the physician needs to search for the correct proxy according to the patient's wishes and state law, when there is time to do this.
- Suffering is not the same as physical pain. The body experiences pain, whereas persons experience suffering, particularly when physical changes threaten their future.
- Patients have individual perceptions of burdens and benefits when they live with chronic illnesses. The only way to understand a person's quality of life and whether treatment is "right" for a patient is to have a conversation to explore his or her wishes and values.
- An important aspect of the initial ED evaluation of a patient with a life-limiting illness is to ascertain the patient's general wishes for future resuscitation and treatments. The conversation with family and patient can begin by asking the following questions: What kind of resuscitation do you wish to receive if an emergency occurs after admission? Whom do you want to make decisions for you if you cannot?
- A discussion of goals of care is more effective if it starts by clarifying the patient's broad values and goals. From the broad discussion, the clinician can suggest what procedures may or may not be useful in attaining the patient's goals.
- The purposes of hospitalization for persons with severe terminal diseases should be clear and in line with the patient's values.

Emergency Medical Treatment and Active Labor Act and Medicolegal Issues

Robert A. Bitterman

PERSPECTIVE

Practicing good medicine in the emergency department (ED) may have been enough to avoid legal entanglements historically, but no longer. Federal and state laws now directly govern the practice of emergency medicine. The magnitude and complexity of the controlling legal authority plus the significant penalties for noncompliance, such as criminal sanctions, civil lawsuits, civil monetary penalties, and exclusion from participation in Medicare and Medicaid, dictate that emergency physicians acquire functional knowledge of these laws.

Federal law—the Emergency Medical Treatment and Active Labor Act (EMTALA), a section of the Consolidated Omnibus Budget Reconciliation Act of 1985 (COBRA), also known as the "antidumping" statute—governs how emergency physicians must triage, register, examine, provide workup, treat or stabilize, discharge or transfer, use hospital resources, and involve medical staff expertise when caring for patients presenting to the ED.[1-3] State laws further control the practice of emergency medicine through such issues as consent, reporting requirements, confidentiality requirements, forensic and police matters, civil commitments, and emergency medical services (EMS) statutes.

EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT (EMTALA)

EMTALA originally was enacted to prevent private hospitals from refusing to treat indigent patients with medical emergencies or transferring ("dumping") them in an unstable condition to public hospitals. Subsequent amendments to the law, government regulations, and court decisions greatly expanded the reach of EMTALA, such that the law now sets national standards for the provision of emergency services.[2-4] Today, emergency physicians must have a solid understanding of EMTALA's statutory requirements and how the regulatory agencies and the courts interpret the three main aspects of the law: screening, stabilizing, and discharging or transferring ED patients.

Medical Screening Examination

Any person who comes to an ED requesting examination or treatment for a medical condition must be provided with an appropriate *medical screening examination* (MSE).[5] The purpose of the MSE is to determine whether the patient has an *emergency medical condition* (EMC).[6,7]

Emergency Medical Condition

EMTALA defines an EMC as "acute symptoms of sufficient severity (including severe pain) such that the absence of immediate medical attention could reasonably be expected to result in (1) placing the health of the individual (or, with respect to a pregnant woman, the health of the woman or her unborn child) in serious jeopardy, (2) serious impairment to bodily functions, or (3) serious dysfunction of any bodily organ or part."[6] In the case of a pregnant woman who is having contractions, an EMC is defined as one in which "there is inadequate time to effect a safe transfer to another hospital before delivery, or that transfer may pose a threat to the health or safety of the woman or the unborn child."[7]

Competent physicians can reasonably disagree as to whether certain conditions are serious enough to constitute an "emergency." However, the courts hold that the relevant factor is whether the physician *perceived* the patient to have an EMC, not whether the patient actually had an EMC and not whether the emergency physician or hospital should have known that the EMC existed. The focus is whether the physician or the hospital did in fact actually determine that the patient had an EMC; the standard is subjective, not objective.[8] If the physician and the hospital perform an appropriate MSE and in good faith determine that no EMC existed, the courts will not retrospectively review that decision; rather, it will be a simple state malpractice issue of whether the examination and diagnosis met the applicable standard of care.

If the MSE does not reveal an EMC, further care of that patient is not controlled by EMTALA, so the law's provisions governing stabilizing treatment, transfer of the patient, or involvement of on-call physicians no longer apply. This interpretation emphasizes the critical importance of documentation of the presence or absence of an EMC during a patient's initial ED evaluation. A check box to indicate such should be on every ED medical record.

"Any Individual"

Everyone who presents to the ED requesting care must be screened. Whether the patient is indigent, a member of a managed care plan, or covered by Medicare, Medicaid, or private insurance is irrelevant; the hospital must provide everyone who presents for care with an MSE.[5] This includes all populations of patients, such as illegal aliens, minors, and private patients of the hospital's medical staff, but excludes persons who are already patients of the hospital, such as inpatients or outpatients undergoing a scheduled procedure at the hospital who are brought to the ED for

www.ketabpezeshki.com 66485457-66963820

emergency care.[2] The screening of minors is discussed later in the section on consent.

Request for Examination or Treatment of a Medical Condition

Mere presence in the ED or on hospital property is not sufficient to trigger the hospital's duty to provide an MSE; a request for examination or treatment also is necessary. The request can be made by *anyone* on behalf of the patient, including EMS personnel, a police officer, or a babysitter; the request does not have to come from the patient, a family member, or a legal guardian.[5]

Also, if a person is unable to speak to request care, that person's behavior may constitute a request if the hospital's personnel are aware of the behavior and a prudent layperson would believe that the behavior indicated a need for examination or treatment.[2]

Private Patients

In many hospitals, members of the hospital's medical staff often meet their private patients in the ED. These patients are examined and treated by their private physicians, not the emergency physician on duty. Such practice is entirely appropriate to maintain physician-patient relationships and is allowable under EMTALA. However, the hospital should have prearranged procedures for handling of private patients that do not unduly delay the patient's MSE; otherwise, the hospital could be liable under EMTALA for failure to provide an "appropriate" MSE. Delay of treatment in such instances also frequently results in hospital liability through state malpractice actions.

Triage of all private patients should be conducted according to the hospital's established protocols. If the triage nurse determines that the patient requires immediate care, the emergency physician on duty should provide the necessary treatment until the patient's private physician arrives in the ED to assume the patient's care.

If triage determines that the patient does not require immediate care, the emergency physician should see the patient in the order consistent with the usual practice of the ED, generally in the order of acuity or time of arrival. If the private physician comes to the ED and sees the patient before the emergency physician does, the examination by the private physician constitutes the required MSE by the hospital. In this situation, no undue delay of the MSE for any nonmedical reason has occurred. However, if the patient's private physician has not arrived by the time the emergency physician would normally examine the patient, the emergency physician should perform an MSE. If no EMC is evident, the patient can wait for his or her physician to arrive. If an EMC exists, the emergency physician should undertake appropriate stabilizing treatment until the patient's physician arrives.[9,10]

"Comes to the Emergency Department"

The Centers for Medicare and Medicaid Services (CMS) deems anyone on hospital property to have "come to the emergency department."[11,12] According to CMS, "hospital property" consists of the entire main hospital campus, including parking lots, sidewalks, and driveways, and any ambulance owned and operated by the hospital, even if the ambulance is not on hospital grounds.[12] CMS then divides hospital property into "dedicated emergency departments" and all other property that is not a dedicated ED.

A *dedicated* ED is defined as any department or facility of the hospital, whether on or off campus, that is licensed by the state as an ED; is held out to the public as a place that provides care for persons with EMCs on an unscheduled basis; or actually does provide care for persons with EMCs a certain percentage of the time.[2] Units qualifying as dedicated EDs include typical hospital EDs, labor and delivery units, and psychiatric intake centers.

CMS also intended EMTALA to apply to urgent care centers. However, urgent care centers do not hold themselves out as able to provide care for EMCs as defined by the statute, nor do they in actuality provide care for a sufficient number of true emergencies to meet the regulatory percentage. Thus the typical urgent care center is not likely to meet CMS's regulatory definition of a dedicated ED and therefore will not have to comply with EMTALA. Hospitals should examine how their relationship with any urgent care center is legally structured in conjunction with the regulations to determine whether EMTALA applies.[2,13]

CMS specifically exempts a number of on-campus areas from compliance with EMTALA—in general, those areas that typically do not provide emergency care, such as physicians' offices, skilled nursing facilities, other entities that participate separately under Medicare, and other nonmedical facilities on campus.[2] CMS also exempts application of the law to off-campus facilities and other "departments of a provider" that were never intended or structured to manage EMCs, such as dialysis centers, rehabilitation units, laboratories and radiology centers, and primary care clinics. However, these facilities must have written policies and procedures for appraisal of emergencies and arrangement of transfer when it is appropriate.[14,15]

Presentations to the hospital's dedicated ED require only a request for examination or treatment of a medical condition; it is not required that the presentation be for a medical condition that constitutes a true emergency to trigger EMTALA's screening duty. Presentations to hospital property other than to the dedicated ED do, however, require the request to be for an EMC before EMTALA applies.[2]

"Parking" of Patients Brought by Emergency Medical Services to the Emergency Department

Overcrowding led some hospitals to ignore ambulance patients, leaving EMS to care for them until the hospital "accepted" the patient, a practice termed EMS "parking." These hospitals erroneously believed that unless they accepted responsibility for the patient, they had no EMTALA duty to provide care or to accommodate that patient. CMS issued a memorandum reminding hospitals that their EMTALA obligation begins the moment the patient "comes to the ED" and a request is made on behalf of the patient for examination or treatment of a medical condition, not when the hospital "accepts" the patient.[16] Of note, the practice of parking EMS patients also may violate Medicare regulations, which require hospitals to "meet the emergency needs of patients in accordance with acceptable standards of practice."[17]

CMS later clarified that its parking memo did not mean that hospitals are required in all instances to take instant custody and responsibility of all patients brought in by EMS, stating that its guidance "should not be interpreted to mean that a hospital cannot ever ask EMS staff to stay with an individual transported by EMS to the hospital when the hospital does not have the capacity or capability to immediately assume full responsibility for the individual."[18] CMS noted that in certain circumstances, such as an influx of multiple trauma victims, it would be reasonable for the hospital to ask the EMS provider to stay with the patient until such time as the ED staff became available to care for that person.

CMS did affirm, however, that "even if a hospital cannot immediately provide an MSE, it must still triage the individual's condition immediately upon arrival to ensure that an emergent intervention is not required and that the EMS provider staff can appropriately monitor the individual's condition." CMS reviews complaints of this nature on a case-by-case basis to determine whether the hospital violated EMTALA's medical screening mandate.[18]

www.ketabpezeshki.com 66485457-66963820

National Emergencies or Disasters

Under certain circumstances, the Secretary of Health and Human Services can exempt hospitals from EMTALA during times of national or local disasters or terrorist acts, bioterrorist events, or pandemic infectious disease.[19,20]

Other Emergency Department Functions

Hospital EDs serve many functions other than the evaluation and treatment of patients with true medical emergencies. Physicians on the hospital staff may use the ED in the off-hour periods to provide injections or to obtain laboratory tests or radiographs for their patients. Police use the ED to obtain blood alcohol samples on allegedly intoxicated automobile drivers. Some hospitals may use the ED to provide urine drug screens of injured workers, prescription refills, allergy injections, rabies vaccinations, blood transfusions, or other community medical services (e.g., blood pressure screening or "flu shots").

Laboratory Tests and Radiography Requests

The test category includes urine or serum drug screening, routine laboratory tests, and imaging studies. In each case, no immediate medical decision-making is required. The patient's physician determines the indication for the studies and is responsible for the patient's care, including following up on the test or radiography results. The patient is not requesting "examination or treatment for a medical condition" by the hospital's ED, so the hospital does not need to provide an MSE.

Such patients should not be sent through triage and should not have their vital signs taken, and the hospital should not create the usual ED chart for them. They should not be asked to sign the usual ED "consent for treatment" forms, which could imply that they were requesting examination and treatment. Separate paperwork should be used to document the visit, the particular test performed, the patient's informed consent for the testing, any communication with the private physician, and a specific statement that the patient is not requesting an MSE from the ED, with the patient's signature.

Some persons come to the ED on their own, not at the request of their physician, and request a test (e.g., for pregnancy or human immunodeficiency virus serostatus). All such persons should be given an MSE before any test is conducted. If the person declines the MSE, he or she should be referred elsewhere to obtain the requested test: outpatient clinic, personal physician, or public health clinic or a local drugstore for a pregnancy test. Documentation that the person declined the offered MSE is essential.

Minor Treatments

The minor treatment category includes allergy injections, tetanus immunization, rabies vaccination, bloodletting or blood transfusions, chemotherapy infusion for cancer or possible organ transplant rejection, reinsertion of a feeding tube or Foley catheter, prescription refills, suture removals, antibiotic injections, and narcotic injections for chronic pain syndromes. Patients presenting to the ED requesting treatment should be given an MSE. In each instance, the common denominator is the element of medical decision-making.

Antibiotic and narcotic injections require special comment. Physicians, particularly in rural hospitals, may send their patients to the ED and then call in phone orders for parenteral medications. If such patients are not examined by the emergency physician on duty, it probably violates EMTALA because the hospital is not providing these patients the same MSE as it would for any other patient with the same complaint. It is irrelevant if the patient's private physician performed an office examination immediately before sending the patient to the ED. This requirement of EMTALA may not be cost-efficient medicine, but both CMS and the courts agree that a hospital is required to provide an MSE to any person who comes to the ED and requests examination or treatment for a medical condition.[1,21]

All patients presenting for minor treatments should be triaged, registered, and managed as all other ED patients are. The ED evaluation should determine whether the patient's condition meets the definition of an EMC before the hospital administers any medications. CMS and the courts will assume that these patients requested examination or treatment, and the hospital must demonstrate that either (1) these patients did not request that an MSE be performed or (2) the ED evaluation did not reveal an EMC.

Fundamentally, the hospital still must perform an MSE to the extent necessary to determine whether an EMC exists, regardless of whether the patient's presenting complaint appears to be trivial or for a "nonemergency" condition.[2,13]

Prescriptions

In small communities, local pharmacies frequently are not open continuously. Hospital pharmacies, sometimes through the hospital ED, fill prescriptions for patients in off-hours. Patients presenting to the ED to fill these prescriptions do not need an MSE. If the prescription is filled through the ED, the hospital should have the patients sign a form indicating that they are not requesting an MSE, for the same reasons and in the same manner as when tests are done in the ED at the request of physicians.

This situation is different from that in which patients present to the ED for prescription renewals. Patients requesting "refills" on this basis are seeking not pharmacy services but medical decision-making services from a physician by asking for a prescription renewal to treat an underlying medical condition.[2,9] Therefore, patients seeking prescription *renewals* must be provided with an MSE.

Sexual Assault Cases

The ED often assists police in the collection of evidence related to alleged sexual assault cases. If a person comes to the ED solely to provide evidence for the criminal investigation and is not requesting examination or treatment for a medical condition, no MSE is required. However, if the person complains of pain or injury or wants pregnancy or sexually transmitted disease prophylaxis, that person is requesting examination or treatment for a medical condition and must be provided with an MSE.[22]

Preventive Services

Blood pressure screening and vaccination services do not require an MSE. The patient receiving such services is not requesting examination or treatment for a medical condition. The patient is attempting to prevent illness prophylactically, not seeking treatment of an illness. These vaccinations are distinct from tetanus boosters, because boosters typically are administered in response to injury and represent a component of medical decision-making and treatment.

Police Blood Alcohol Tests

For both medical and legal reasons, an MSE should be offered to all persons presenting to the ED for police-requested blood alcohol samples.[23] This scenario is different from that in which patients present to the ED to have blood tests done as ordered by their physicians. Persons in police custody have not been examined by

www.ketabpezeshki.com 66485457-66963820

a physician, and the results of the test will not be returned to a physician to care for the patient. The police officer brought the patient because of aberrant behavior, suspected to be caused by alcohol intoxication. Many diseases mimic alcohol intoxication, including hypoglycemia, cerebral hypoxia, head injury, metabolic abnormalities, and other toxins. Medically, alcohol intoxication should not automatically be presumed as the cause of the patient's condition merely because it is so common. The emergency physician should examine the person in custody to determine if an EMC exists.[9]

The patient may refuse the MSE and request that only the blood be drawn. If the patient appears competent, this can be done. The refusal of the MSE must be documented, as noted for other testing done in the ED, with additional documentation of the risks and benefits of the offered MSE and careful notation of the patient's competence. If the patient is too intoxicated to make medical decisions, release from the ED should be delayed until the patient is competent enough to make rational decisions. Only physicians should assess and document a patient's competence; other ED personnel should not be allowed to make these decisions.[9]

Again, under EMTALA, the "request for examination or treatment" can be made by anyone on behalf of the patient. The police officer's request for blood alcohol sampling may be sufficient to constitute the request for an MSE.

Health Care Providers Qualified to Perform the Medical Screening Examination

EMTALA does not specify whether a physician, a nurse, or another health care provider must perform the MSE. CMS regulations require that the screening examination be done by "qualified medical personnel"[24] and that the hospital's governing body formally designate, in writing, who is a qualified person to perform medical screening on behalf of the hospital.[25,26] CMS specifies that the hospital cannot allow the medical director of its ED to designate who is qualified to perform screenings on behalf of the hospital.[27]

Triage by a nurse does not constitute an MSE, even for "obvious" nonemergent conditions. Neither CMS nor the courts accept triage as adequate to determine whether an EMC exists.[2,3,9]

It is strongly recommended that hospitals designate physicians to be primarily responsible for MSEs performed in the ED. Either the physician personally performs the screening or is directly responsible for examinations performed by physician assistants (PAs), nurse practitioners (NPs) or house staff. It is appropriate to use PAs and NPs to screen patients who are determined by nurse triage to have less acute or severe conditions. However, the physician on duty should have a direct supervisory role with the PA and a collaborative arrangement with the NP.

Ancillary Services as Part of the Medical Screening Examination

The law requires hospitals to provide the screening examination "within the capabilities of the hospital's emergency department, including ancillary services routinely available to the emergency department."[5] According to CMS, this means that the scope of an MSE may "range from a simple process involving only a brief history and physical examination to a complex process that also involves performing ancillary studies and procedures such as (but not limited to) lumbar punctures, clinical laboratory tests, CT scans, and/or diagnostic tests and procedures."[28]

Because the stated purpose of the MSE is to determine whether an EMC exists, CMS and the federal courts hold that the hospital must conduct whatever examination is necessary to make that determination.[3,29] It may take only a visual glance to rule out an EMC in a patient with a rash. However, if it takes a complete neurologic examination, computed tomography scan, and lumbar puncture to decide whether a headache patient has a subarachnoid hemorrhage, then those procedures are considered part of the MSE.

Thus, if the ED usually has ultrasonography, computed tomography, ventilation-perfusion scans, and similar tests available, it must use those resources *if necessary* to determine whether the patient has an EMC. However, the hospital is obligated to use only the resources ordinarily available to its ED.[5] Neither the statute nor the regulations mandate that hospitals expand resources or offer additional services to ED patients. An exception may be the use of interpreters for patients not fluent in the English language, which is required by the Medicare conditions of participation.[30,31]

CMS views the ancillary services available to the ED as including the services of on-call physicians if their expertise is required to decide whether the patient has an EMC.[2,9,13,28,30,32] If the emergency physician cannot determine whether a patient has an EMC, the physician must use the on-call physician services to help make that determination. For example, if it takes an on-call surgeon to decide whether a patient has an "acute abdomen," the surgical evaluation becomes an integral part of the hospital's MSE.

Policies, Procedures, and Practice Guidelines

The federal courts hold that an appropriate MSE has two components: (1) the examination must be "reasonably calculated to identify critical medical conditions" and (2) the "exact same level of screening must be uniformly provided to all patients who present with substantially similar complaints."[29] In other words, a hospital satisfies the requirements of EMTALA if it conducts standard screening procedures, uniformly, for all patients with similar complaints and circumstances.

Each hospital determines its own standard screening policies and procedures. By necessity, each hospital's standard will be individualized because each hospital ED has its own capabilities and different ancillary services available. Once a hospital defines its standard screening process, however, it must apply that process uniformly to all patients presenting with similar complaints, and material departure from its standard screening procedure constitutes inappropriate screening under EMTALA. Because motive is not a relevant issue in the federal courts (except the Sixth Circuit Court) or during CMS investigations, liability may result from any material deviation of the hospital's screening process, regardless of the hospital's motive and regardless of the reason for the deviation. For example, a Florida hospital's screening policy stated that triage would be conducted within 3 minutes after a patient's arrival at the ED. In one instance, a patient was not triaged until 45 minutes after arrival; this delay constituted a violation of the law because the hospital did not follow its own policy.[9]

Once hospitals define their own standard screening process, they will be held to that standard, by both plaintiffs and the government enforcers. Investigators and plaintiff attorneys will subpoena and closely examine the hospital's policies and procedures, medical staff bylaws, ED rules and regulations, practice guidelines, and other written information on the screening process. They will compare the written process to what actually transpired. These hospital documents must be drafted very carefully to avoid unintended liability.

Practice guidelines or protocols, including managed care manuals, adopted by EDs or hospitals may be treated essentially the same as the hospital's own policies and procedures. They also are routinely used to demonstrate that the hospital "failed to follow its own rules" when hospitals and physicians do not adhere to their adopted parameters. In fact, practice guidelines are used *against* physicians and hospitals much more frequently than they are used to their benefit in malpractice litigation.[33]

www.ketabpezeshki.com 66485457-66963820

Registration Process, Collections or Insurance Information, and Authorization

CMS does allow hospitals to conduct reasonable registration procedures in the ED, including collection of insurance data or cash at the time of registration, as long as the process does not delay the MSE. A reasonable registration process may obtain demographic data and the name of the patient's physician and determine whether the patient is insured and the type of insurance. During the registration process, the patient can sign the hospital's usual "informed consent to be examined" form and a routine form that holds the patient financially accountable for any charges not covered by the patient's insurance carrier.[2]

The key is to create parallel tracks for medical and financial issues and to ensure that the financial track never interferes with the medical care in any way. "Bedside registration" probably is necessary under the existing regulatory scheme to avoid "no-delay" violations because CMS would consider any delay in access to the MSE due to diversion to the registration area to be against the law. Waiting for examination and treatment because the ED is overwhelmed is not a violation, but waiting for examination because the registration clerks are collecting insurance information probably is a violation.[2]

CMS warns hospitals not to coerce patients into leaving before they receive their federally guaranteed MSE, stating "reasonable registration processes may not unduly discourage individuals from remaining for further evaluation."[2] Collection of copayments, down payments, advanced beneficiary notifications, or signatures on managed care financial forms may constitute such "economic coercion" if it is not done very carefully. Hospitals also should ensure that staff behavior does not create a hostile environment or constructive denial of the MSE.

Furthermore, hospitals should never delay a patient's MSE to obtain prior authorization from a managed care organization (MCO). First, managed care authorization is authorization for payment only—it is not authorization for treatment, and second, CMS explicitly bans prior authorization for managed care plans before completion of the MSE and commencement of stabilizing treatment.[2] Hospitals may obtain authorization for payment from insurance entities only "concurrently" with stabilization of the patient.[2,27] Hospitals are legally obligated to provide the MSE, and they will be held to that standard regardless of the financial pressures placed on them by MCOs. (As a related issue, "Managed healthcare plans cannot deny a hospital permission to examine or treat their enrollees. They may only state what they will and will not pay for, and regardless of whether a hospital is to be reimbursed for the treatment, it is obligated to provide the services specified in EMTALA."[27])

Patients often ask questions about their obligation to pay for emergency services, particularly whether their insurance will cover the visit or how much it will cost to receive care at the ED. Regardless of EMTALA, all patient questions should be answered forthrightly, honestly, and completely by the hospital staff. In general, routine financial questions can be answered by registration personnel or triage nurses trained to give "stock answers," to not discourage or coerce the patient in any way, and to encourage the patient to stay, with discussions of payment deferred until after an MSE is performed.

After the hospital answers the patient's questions, the patient is responsible for making informed decisions about further aspects of care. If a patient chooses to withdraw a request for examination or treatment and to leave the ED, hospitals need to carefully handle the interaction related to the patient's "voluntary withdrawal" (see the later section on consent). Whenever the patient intends to leave, the staff should involve the physician on duty.

Regardless of managed care status, "VIP" status, private patient status, or any other classification, all patients should be processed in the same manner.[34,35] In addition, the triage team, physician and nursing staff, and all clinical personnel should not know the patient's insurance status throughout the initial screening and stabilizing treatment. This removes insurance status as an issue should the government later claim that the staff was motivated in some way or treated the patient disparately on the basis of financial class. It is easier to prove that actions were not predicated on the patient's financial status when the staff lacked knowledge of that status than to prove that the actions were medically appropriate despite knowledge that the patient had no insurance.

After the MSE and initiation of stabilizing treatment, insurance status and ability to pay can be considered in determining the patient's future care, such as hospital admission, transfer, or discharge and follow-up.

Documentation

EMTALA is a technical law, and compliance with the technicalities requires proper documentation. Furthermore, clinical outcomes are irrelevant under government enforcement, and compliance is not presumed; hospitals must prove compliance through documentation.

Central Log

Hospitals must maintain a central log of all patients presenting to the ED requesting examination or treatment. The log must contain the name and disposition of the patient, including whether the patient refused treatment, whether the hospital refused to provide an MSE or treatment, and whether the patient was treated and stabilized, admitted, transferred, or discharged.[36] The purpose of the log is to permit CMS and state surveyors to select and review individual records to investigate whether the hospital is in compliance with the law.[28]

The log must include all persons presenting to the hospital's dedicated EDs, whether on or off campus.[2,36,37] These areas include the typical ED, ambulatory care or fast-track areas contained within the ED, freestanding emergency centers, labor and delivery suites, and psychiatric intake centers.[2] The logs are not required to be collated into a single document but must be retrievable at CMS's request.

Medical Record

All areas of the hospital used to conduct the MSE must create a medical record for the patient and keep a log of those presenting for examination and treatment.[38] If members of the hospital medical staff see their patients in the ED, on either a scheduled or an unscheduled basis, the hospital must create a medical record and require the physician to document the care provided in that record. The physician's private office records documenting care provided at the hospital are insufficient.

Most important, the emergency physician should document whether an EMC was determined to exist for *every* patient seen in the ED, even if the initial chief complaint is seemingly trivial. The legal purpose of the required MSE is to determine if an EMC is present. To facilitate documentation, ED charts should include two check boxes: one labeled "EMTALA EMC present" and the other "EMTALA EMC absent." The person performing the MSE should check the appropriate box for each patient, and completion of this documentation should be a prime part of the ED's quality improvement monitoring program.

Stabilization Requirements

Once the hospital determines that an individual has an EMC, EMTALA requires the hospital either to stabilize the EMC or, if it

www.ketabpezeshki.com 66485457-66963820

lacks the capability to stabilize the patient, to transfer the patient to another medical facility that can provide the necessary treatment.[39] A sample form for use in documenting such transfers and patient consent to transfer is shown in Figure 1.

When and if the patient is "stabilized" has significant ramifications for hospitals and physicians because once patients are stabilized, EMTALA no longer applies.[40] After stabilization, hospitals are free to refuse to provide further treatment or to transfer stabilized patients for purely financial reasons. On-call physicians can refuse to treat or to admit stable patients or insist that stable patients be transferred owing to their lack of or type of insurance. An MCO can refuse further payment to the hospital and request that the stabilized patient be transferred to one of its contracting facilities.[41,42]

However, other federal, state, or local standards may govern further treatment or transfer of ED patients. For example, state laws often prohibit hospitals from transferring patients for any reason except that they are incapable of handling the patient's medical problem.

Two elements must be present to trigger EMTALA's stabilization requirement: (1) the patient must have an EMC, as defined by law, and (2) the hospital must determine that an EMC exists. That an EMC exists is not sufficient to invoke the duty to stabilize; the hospital also must have actual knowledge that the EMC is present. *Actual knowledge* is a legal term that means the examining physician subjectively believed that an EMC existed. It is not the commonly understood objective standard used in malpractice cases, wherein liability is predicated on whether the physician knew or reasonably should have known that the patient had an emergency condition. Whether the physician's judgment was negligent, or even grossly negligent, is irrelevant under EMTALA. The *subjective perception* of the examining physician controls whether EMTALA's stabilization requirement is triggered.

The appellate courts have uniformly held that if an EMC is not detected, the hospital has no stabilization duty and cannot be charged with failure to stabilize the patient's condition.[8,9,43,44] Furthermore, consideration or suspicion that an EMC may exist does not rise to the level of actual knowledge. If the hospital fails to detect an EMC through its standard screening procedures, the patient has only a state malpractice claim of "failure to diagnose" and not a federal cause of action for "failure to stabilize" the emergency condition. Once the physician or hospital does diagnose an EMC, however, the courts will allow a failure-to-stabilize claim to be brought in federal or state court under EMTALA.

This aspect of EMTALA is distinctly different from ordinary malpractice. Documentation in the medical record of "no EMC present" eliminates all further liability under EMTALA; understanding and use of this distinction should be part of every ED's risk management program.

The screening section of EMTALA mandates the hospital to provide only those services within the capability of the *ED,* including ancillary services routinely available to that department.[5] The stabilization section, however, requires the level of services within the capabilities of staff and facilities available at the *hospital.*[45]

The capabilities of the hospital staff include whatever intensity of care the personnel of the hospital can provide within the training and scope of their professional licenses and hospital privileges.[27] To ensure that hospitals can stabilize patients, Congress mandated that Medicare-participating hospitals maintain a list of on-call physicians available to provide treatment necessary to stabilize a patient with an EMC.[46]

Thus, whenever the ED determines that a patient has an EMC, the hospital must use the full capabilities of its staff, facilities, and on-call physicians to stabilize the patient.[2,45] If the hospital is unable to stabilize the patient, a physician must certify that a transfer is medically indicated and arrange an "appropriate" transfer to a higher level facility.

The treating physician needs to decide whether a patient's EMC is stable or unstable. If two physicians disagree about whether the patient is stable but only one of the physicians is at the bedside caring for the patient, the on-site physician should make the decision.[2,9] It is *not* appropriate for an on-call physician, a "managed care gatekeeper" physician, a physician at a receiving facility, or even the patient's regular attending physician to disagree with the decision of the on-site physician over the phone. If one of these outside physicians wants to overrule the determination of the on-site physician, he or she must come to the hospital and personally examine the patient.

EMTALA defines the term *stabilized* as follows: "no material deterioration in the condition is likely, within reasonable medical probability, to result from or occur during the transfer of the individual from a facility."[47] For a pregnant woman having contractions who has an EMC, stabilized means that delivery (including the placenta) has occurred.[48]

This is a *legal* definition of stabilization, not a medical definition. The standard of care for any patient diagnosed with an EMC will be judged by this legal definition, not by the usual medical malpractice standards. This is a national standard under federal law, not a local standard under state malpractice law.[9,48]

The question of "stabilization" typically arises only when the patient deteriorates during or after the transfer and experiences an adverse medical result. It is likely to appear, particularly in hindsight, that the patient was not completely stabilized before transfer. Health care providers should remember that their compliance usually will be judged by an unsympathetic jury, aided by hindsight, in the context of impairments suffered by the patient in an adverse medical outcome. Unfortunately, the court system, not the health care system, will ultimately determine when a patient with an EMC is legally "stabilized."[9,48]

The U.S. Supreme Court, in the case of *Roberts v Galen,* ruled that a plaintiff need not show improper motive for a transfer to prevail on a failure-to-stabilize claim under EMTALA. The plaintiff merely must prove that the patient was not properly stabilized before the transfer.[49]

EMTALA's requirement to provide on-call physicians no longer extends to inpatients diagnosed with an EMC.[2] Other Medicare conditions of participation govern inpatient care, and hospitals certainly should implement policies and procedures to provide emergency specialty services to patients in whom an EMC develops after admission to the inpatient setting.[2]

Disposition Issues under EMTALA

Admission

Once the emergency physician determines that a patient needs to be hospitalized, the patient's physician or the appropriate on-call physician should be contacted. If the admitting or on-call physician disagrees with the emergency physician's judgment, it is incumbent on the admitting or on-call physician to come to the ED to personally examine the patient. This fact should be mutually understood by the entire medical staff and the hospital administration and should be written into hospital policy and procedure.

Direct patient admissions are problematic. In the three most common scenarios, the patient (1) is sent to the ED after being examined by the primary care physician (PCP) in the office, (2) is sent in after phone contact with the PCP, or (3) is accepted by phone-in transfer from a different hospital ED or inpatient setting by the PCP. In all three cases, the PCP intends to see the patient after admission to the inpatient setting rather than in the ED. Medically, each presentation may require a different level of acute intervention, but legally all are the same under EMTALA.[2,3,13] CMS does not apply the law to *inpatients* regardless of whether they are

directly admitted to the unit, directly admitted by way of the ED, or "boarded" in the ED awaiting bed placement. Even if the inpatient is brought down to the ED, the law does not apply.[2,3,24] According to CMS, once a hospital admits the individual in good faith (i.e., the admission is not a ruse to avoid liability under the law) as an inpatient for further treatment, the hospital's obligation under EMTALA ends.[44,50]

An *inpatient* is defined as "an individual who is admitted to a hospital for bed occupancy for purposes of receiving inpatient hospital services … with the expectation that he or she will remain at least overnight."[2] It does not matter if the situation changes later and the patient can be discharged or transferred to another hospital and does not actually use the bed overnight. The key element is that the patient be formally admitted with a documented admission order. A physician's intent to admit or a level of acuity indicating that the patient "obviously will be admitted" is not enough to satisfy the definition. Documentation is critical.[2,24]

CMS does not consider patients admitted to observation status to meet the regulatory definition of admitted patients (not admitted for purposes of receiving inpatient services), so EMTALA still applies to the care of observation patients, such as patients managed in ED chest pain or observation units.[2,24] Therefore, under existing government regulations, persons who were directly admitted and sent through or held in the ED from a physician's office, from a nursing home, or in transfer from another ED or another hospital inpatient setting are no longer covered by EMTALA, even though they have "come to the hospital's emergency department."

However, in 2009 the Sixth Circuit Court of Appeals in the case of *Moses v Providence Hospital* rejected CMS's interpretation, and, giving no deference to the agency's rulemaking authority, it overruled CMS's regulation[51] that EMTALA ended when the hospital admitted the patient in good faith. The court determined that the rule was contrary to EMTALA's plain language,[52] which requires a hospital to "provide … for such further medical examination and such treatment as may be required to stabilize the medical condition."[53] Therefore, the Sixth Circuit Court held that the hospital was required under EMTALA not just to admit the patient into an inpatient unit for further care but to actually treat him such that he was stabilized before discharge.[53] Subsequently, the U.S. Supreme Court declined to review the controversial Sixth Circuit decision in *Moses,* so presently in the states of Michigan, Ohio, Tennessee, and Kentucky, EMTALA applies to inpatients, at least for civil litigation purposes, even if CMS will not apply that law to inpatients for regulatory purposes.[53,54]

In *Moses,* the issue was whether EMTALA applied to the discharge of a psychiatric patient from the hospital inpatient setting, many days after he had been admitted through the ED for stabilizing care. After discharge, the patient went home and later murdered his wife, so the family sued Providence Hospital under EMTALA for failure to stabilize the patient before discharging him home. Because EMTALA defines all discharges from the hospital as "transfers," regardless of whether the discharge is from the ED or inpatient setting,[55] the plaintiff's claim was for "failure to stabilize the patient prior to transfer" as required by EMTALA.[53]

In response to the *Moses* case, CMS published, in late 2010, an "advanced notice of proposed rulemaking" soliciting comments on whether it should rewrite two key rules on the application of EMTALA to hospital inpatients.[56]

Q1. Should EMTALA apply to hospitals that admit patients for stabilizing care?

Q2. Should hospitals with specialized capabilities be required to accept patients in transfer after they have been admitted at another hospital?

The second question was posed because in 2008, CMS had issued a rule that hospitals with specialized capabilities did not have an EMTALA obligation to accept the appropriate transfer of an individual who had been admitted in good faith as an inpatient at the first hospital.[57] In other words, because EMTALA ended for the hospital that admitted the patient, no other hospital had an EMTALA duty to accept the patient in transfer, even if the admitting hospital was not able to stabilize the patient.

If the Sixth Circuit's decision in *Moses* is allowed to stand, it would void CMS's regulation that hospitals are not required to accept inpatients in transfer. If EMTALA continues through admission until discharge, CMS loses its basis for claiming that hospitals do not have to accept inpatients with emergency conditions in transfer.[56,58] As of the date of this writing, CMS had not issued any final new rules regarding the application of EMTALA to inpatients.

"Discharge" or "Transfer" to Home

Because EMTALA defines any patient movement away from the hospital as a transfer,[55] all patients discharged from an ED are legally considered to have been transferred. Sending a patient home after treatment in the ED who is retrospectively determined to be unstable is considered to represent a transfer of an unstable patient and, as such, a violation of the law. This exposes the hospital to civil litigation under EMTALA for failure of its emergency physicians to stabilize patients with known emergency conditions before discharge ("transfer") home.[1,49]

To avoid such retrospective analyses, emergency physicians should document that no EMC was found or that the patient was stable on discharge. If the patient leaves without permission, the hospital has not legally transferred the patient.[55]

"Discharge" or Transfer from the Emergency Department to an On-Call Physician's Office

Because all discharges from the ED are defined as transfers under EMTALA, so too are discharges from the ED sent directly to an on-call physician's office for acute intervention. CMS looks askance at transfer of patients away from the hospital to a physician's office for acute procedures that could have been done in the ED or in the hospital.[21,59] Ophthalmologist services may constitute an exception because although the ED may have rudimentary eye tools, ophthalmologists typically have much better equipment in their offices for examination of patients with eye complaints to determine whether an EMC is present or to treat emergency conditions. In essence, movement to the office in these cases becomes a medically indicated transfer to receive a higher level of services than the hospital can provide. CMS accepts such movement, so long as the ED arranges a formal transfer in compliance with EMTALA, as noted later.

CMS's view is extremely unsatisfactory, particularly to orthopedic surgeons. It is standard practice in most hospitals for the emergency physician to splint various displaced fractures and send the patient to the on-call orthopedic surgeon's office for reduction of the fracture and further necessary treatment. CMS believes that the orthopedic surgeon should perform the reduction and treatment at the hospital in each case because the surgeon's office has no resources that the hospital lacks.

However, EMTALA applies only if the EMC is unstable at the time of transfer.[1,9] If the ED "stabilizes" the fracture, EMTALA's obligations end. Thus it is reasonable to send patients to the office for further treatment, so long as they meet the legal definition of "stable at the time of discharge" from the ED. The determination of whether the patient is stable for transfer to the orthopedist's office rests solely on the judgment of the examining emergency physician. If the patient has accompanying injuries or is too uncomfortable to be moved, or if the emergency physician believes the injury is such that the patient should not travel, then the orthopedic surgeon should be asked to care for the patient in the ED.[9]

www.ketabpezeshki.com 66485457-66963820

Follow-up Care

Obtaining follow-up care for discharged ED patients, particularly indigent persons and Medicaid recipients, is a significant problem for nearly every hospital. However, EMTALA does not reach the on-call physician's office in this scenario. If the patient does not have an EMC or is stable at the time of discharge, EMTALA does not apply from that point forward, and the on-call physician has no legal duty *under EMTALA* to see the patient in the office.

The real issue in ED follow-up is the level of commitment the hospital and medical staff are willing to make to the community. If the administration, the board, and the medical staff are comfortable with their decision and if they have acted in the best interests of the patients they serve, they should have no trouble defending their actions to CMS or any other entity.

Whatever decision the hospital and physicians make about ED follow-up duties, they should explicitly define those responsibilities in the medical staff bylaws or hospital rules and regulations so that all personnel understand, in advance, what it means to be "on call" for the ED at that hospital.

ED discharge instruction sheets also should include a *fail-safe clause* advising patients to return to the ED if their condition deteriorates before seeing the referral specialist or if the follow-up arrangements disintegrate for any reason. Such a statement could help the hospital avoid liability when the on-call specialist fails to implement the prescribed follow-up plan.[60]

Transfers to Other Acute Care Hospitals

Before transferring a patient out of the ED, the emergency physician must first determine whether the patient is stable, as defined by law. EMTALA regulates the transfer of unstable patients only; it does not apply to the transfer of stable patients.[2,9] If no EMC is found, the patient is considered stable. The determination of whether a patient is stable must be made at the time of transfer to be valid under the law.[59] Unstable patients can be transferred for only one of two reasons: if the transfer is medically indicated, or if the patient requests the transfer.[9] There is no "managed care transfer of an unstable patient" or even of a stable patient.

Patients usually are transferred out of the ED because the transferring facility lacks the capability or the resources necessary to treat the identified EMC. Examples of patients best served by transfer are the head-injured patient in a hospital without a neurosurgeon on staff, the pregnant woman who needs the services of a high-risk obstetric center, and the multiple-trauma patient treated initially in a rural ED who requires treatment at a level 1 trauma center.

EMTALA defines such transfers as medically indicated transfers because the purpose of each transfer is to obtain a higher level of medical care necessary to treat the patient's condition that is not available at the transferring facility. EMTALA governs almost every aspect of medically indicated transfers, including requiring hospitals to adopt and to enforce policies to ensure compliance with federal transfer laws and mandating specific actions by the transferring and receiving hospitals (summarized in Boxes 1 to 3).[1-3,9,61-63]

Some states have enacted their own transfer laws.[64] Most state laws parallel EMTALA, but some are even more restrictive, so physicians responsible for patient transfers should be aware of the controlling laws and regulations in their own state as well as federal law.

Box 1 Recommended Procedures for the Transferring Facility

- Stabilize the patient whenever possible.
- Complete a physician certificate of transfer, including the risks and benefits of transfer.
- Obtain the patient's informed consent to the transfer.
- Arrange for another hospital and physician to accept the patient in transfer.
- Send appropriate data to the accepting facility (e.g., medical records, test results, transfer forms).
- Arrange the transfer through qualified personnel, with use of appropriate transportation equipment.
- Maintain records of all transfers for 5 years.

Box 2 Invalid Reasons for Refusal of an Appropriate Patient Transfer

- Lack of insurance or out-of-network managed care plan
- Lack of citizenship
- Veteran status
- Patient's physician not on staff
- Transferring hospital is out of network or outside hospital's defined referral area
- "We are not an affiliated hospital"
- "We are not a specialty hospital"
- "We are a specialty hospital, but that's not our specialty"
- "We are not a 'trauma center' "
- Transfer originating out of county or out of state (including transfer of out-of-state Medicaid patients)
- EMS skipped over closer hospital
- Another hospital refused the transfer in violation of the law
- Another hospital's on-call physician refused to respond to its ED in violation of the law

ED, emergency department; *EMS,* emergency medical services.

Box 3 Recommendations for the Facility Asked to Accept the Patient in Transfer

- Accept all appropriate requests for transfer, regardless of whether the patient is an ED patient or an inpatient of the hospital.
- Have a formal system for accepting or rejecting transfer requests and document the reasons for any refusal to accept a patient in transfer.
- Maintain records of all transfers for 5 years.
- Report all EMTALA transfer violations to CMS.

CMS, Centers for Medicare and Medicaid Services; *ED,* emergency department; *EMTALA*, Emergency Medical Treatment and Active Labor Act.

Duty to Accept Appropriate Transfers from Other Hospitals

Medicare-participating hospitals that have specialized capabilities or facilities are required by EMTALA to accept appropriate transfers of patients who require such capabilities or facilities, if the hospital has the capacity to treat the patient.[65]

The duty to accept patients in transfer is a problematic issue for many larger, tertiary care, or academic hospitals as a result of the on-call specialty coverage crisis in the United States.[66,67] Numerous hospitals have lost full or partial on-call coverage for specialties such as neurosurgery, orthopedic surgery, maxillofacial surgery, neurology, plastic surgery, and hand surgery.[68,69] CMS's softening of its EMTALA on-call regulations in late 2003 accelerated the trend of physicians' simply taking fewer call nights at many smaller to medium-sized hospitals, forcing still more transfers to access emergency specialty care.[3,70,71] As confirmed in recent surveys, these changes have accelerated physician and hospital abandonment of on-call services, increased the risk of harm to patients needing specialty care, caused more delay in patient access to specialty care, and increased the number of patient transfers.[70,71]

www.ketabpezeshki.com 66485457-66963820

Specialty hospitals also enticed physicians away from acute care hospitals, in part because the physicians could decrease their on-call burden. However, CMS now requires specialty hospitals to accept appropriate transfers even if the specialty hospital lacks an ED.[72]

When Must a Receiving Hospital Accept a Patient in Transfer?

A Medicare-participating hospital must accept "medically indicated transfers" if it has "specialized capabilities or facilities" and the "capacity" to care for the patient.[1] *Medically indicated transfers* are ones for which a physician determines the patient has an EMC and needs to be transferred to obtain a higher level of medical care necessary for treatment of the patient's condition that is not available at the transferring facility.[39] *Specialized capabilities or facilities* are essentially any resources, other than a routine admission bed, or physician services available at an accepting hospital but not available at the transferring hospital. *Capacity* is rather generously defined by CMS to include whatever a hospital customarily does to accommodate patients in excess of its occupancy limits. For example, if a hospital customarily moves patients to other units or calls in additional staff, it has in fact demonstrated the ability to provide services to patients in excess of its occupancy limits.[73]

Who Accepts Patients on Behalf of the Hospital?

The duty to accept appropriate transfers is a hospital duty, not a physician duty, and EMTALA does not require that a physician accept the patient.[1] The hospital must create a formal system designating who is authorized to accept or to reject patients on its behalf. It is strongly recommended that hospitals do not use the individual physician on call for each specialty *alone* to accept or to reject patients in transfer. Hospitals should involve an administrative person or an emergency physician in addition to or instead of the on-call physician to avoid inappropriate refusals. Because the duty to accept rests with the hospital, any inappropriate refusal by an uninformed or rogue on-call physician subjects the hospital to termination from Medicare, civil monetary penalties, or civil liability if the patient is harmed because of the refusal to accept the patient in transfer.

The hospital should define the resources and capacity of the institution and the times during which those resources are available. When capacity or necessary resources are not available, the hospital should in a timely manner inform the persons charged with accepting or rejecting transfers. The hospital also should educate appropriate personnel in its known referral facilities on the proper procedure to transfer patients into its system, including informing them of who is and who is not authorized to accept patients in transfer on behalf of the hospital. The hospital is required to educate its medical staff, particularly its on-call physicians and emergency physicians, about their responsibilities under EMTALA, including the responsibility to accept patients in transfer from other facilities on behalf of the hospital.[74]

Does a Hospital Have to Accept Transfers of Inpatients from Other Hospitals?

Current CMS-issued regulations state that no hospital has a legal duty under EMTALA to accept an inpatient in transfer from another hospital. Therefore, even if a requested hospital could treat an inpatient's emergency condition that the transferring hospital is unable to treat, it may refuse the transfer for any reason, including an economic reason, and not be in violation of EMTALA.

However, the issue is certain to be litigated and decided by the courts. It is inevitable that an inpatient will develop an EMC and proceed to die or suffer severe damages because no other hospital would accept the patient in transfer because of lack of insurance. The patient or family will sue the hospital that refused to accept the patient in transfer, claiming that the hospital had a federal duty under EMTALA to accept appropriate transfers of patients with emergency conditions if the transferring hospital could not treat the emergency. The transfer acceptance section of EMTALA was not part of the law when it was originally enacted. Congress later amended the law, calling it the "nondiscrimination" section, because tertiary and academic referral hospitals were refusing to accept patients in transfer from other hospitals, leaving the patients to die in community EDs.[75] This issue was not specifically addressed in the Sixth Circuit opinion in the *Moses* case, although the court's ruling applying EMTALA to inpatients strongly suggests that it would also apply EMTALA's transfer acceptance section to inpatients as well as to ED patients.[53] Thus it still remains to be seen if the courts will ultimately interpret EMTALA contrary to Congress's nondiscrimination intent for patients with life-threatening emergencies.[76]

When Can a Hospital Refuse to Accept a Patient in Transfer?

There are only five reasons for which a hospital can refuse a request for transfer under EMTALA.

First, if the transfer is not a medically indicated transfer, a hospital can decline the transfer.[1] Non–medically indicated transfers include patient-requested transfers and lateral transfers for any reason (*lateral* meaning that both hospitals have the same ability to handle the patient's EMC), such as managed care transfers or family- or physician-requested transfers. Any time the sending facility can handle the patient's EMC, a hospital requested to accept the patient in transfer can lawfully decline.

Second, if the hospital does not have the capacity, as defined by CMS, to accept the patient in transfer, it may and generally should refuse the transfer.[1,2,73]

Third, if the transferring hospital is located outside the boundaries of the United States, the hospital has no legal obligation under EMTALA to accept the transfer.[77] No other territorial limits are imposed on the duty to accept transfers; out of county, out of state, and out of the hospital's designated referral area all are unacceptable reasons to refuse patients in transfer under EMTALA. Moreover, a hospital cannot refuse to accept a transfer just because the sending hospital is "skipping over" other hospitals to send the patient its way.

Fourth, if the transfer is not "appropriate," the hospital may refuse to accept the patient in transfer at that time.[1] This more vague reason takes into account the patient's condition at the time of transfer and the time, distance, and skipping over of other hospitals necessary to reach a receiving hospital. For example, a trauma patient may need intubation and a chest tube inserted before the transfer is appropriate, or traveling 100 miles with hypotension from a ruptured abdominal aneurysm may not be appropriate if closer hospitals are capable of repairing the aneurysm.

Fifth, the patient has been "admitted" to the hospital as defined by CMS (except in hospitals under the jurisdiction of the federal Sixth Circuit Court of Appeals, at least with respect to civil liability, as noted earlier in this chapter.)[1-3,53]

There are no other reasons for which a hospital may refuse a request to accept a patient in transfer from another acute care hospital under EMTALA. Furthermore, no "contingencies" are allowed to be placed on the acceptance of a transfer. The receiving hospital may not condition acceptance of the patient on the transferring hospital's agreeing to take the patient back once the emergency condition is resolved, may not require that the transferring hospital have additional consultations completed before the emergency physician transfers the patient, and may not require the transferring hospital to use the receiving hospital's transport ambulance or helicopter service as a condition for accepting the patient.[78]

www.ketabpezeshki.com 66485457-66963820

Also, refusal of appropriate transfers on the basis of the patient's insurance status or delay of appropriate transfers until the transferring hospital obtains authorization for payment from the patient's managed care plan is definitely illegal under EMTALA.[79]

Duty to Report Transfer Violations

Any time a hospital has reason to believe it may have received a patient transferred in an unstable condition from another hospital, in violation of EMTALA, it must report the transferring hospital to CMS.[80] The duty to report rests with the hospital, so emergency physicians who receive unstable patients in transfer should inform the hospital (risk management or the hospital's legal counsel), which then can determine the appropriate action.

CONSENT FOR MEDICAL CARE

Informed Consent

The doctrine of *informed consent* is a fundamental principle of the American legal system: "Every human of adult years with a sound mind has a right to determine what should be done with his own body."[81] Physicians may not examine or treat any person without consent, and that consent must be informed. This means that the patient must be given all pertinent ("material") information concerning the nature, risk, and alternatives of the treatment before that patient can be deemed to have effectively consented to the medical intervention.

Physicians should endeavor to obtain informed consent yet remain cognizant of the significant limitations on and multiple exceptions to the doctrine, especially in the ED setting. Delaying treatment in an emergency to obtain informed consent is a much more serious and common medicolegal problem than failure to obtain proper informed consent.

The law of informed consent contains a great deal of uncertainty, with many gray areas. Different states have different views, either in their statutory laws (legislation) or in their common law (judge-made law or precedent), on the meaning of "informed consent" in the care of the ED patient. Most cases are unique and depend on the specific circumstances.

Emergency physicians rarely have time to seek legal consultations, let alone wait for a court to render a decision concerning the legal nuances of consent issues. In these situations, it is helpful for emergency physicians to use a *when-in-doubt rule* to guide their immediate actions. This rule simply states that when emergency physicians are in doubt about the legality of a situation, "they should do what they believe to be in the patient's best interest and worry about the legal consequences later." Although emergency physicians risk criminal and civil charges of false imprisonment, battery, and even negligence for failure to obtain appropriate informed consent, the courts almost universally rule in favor of physicians who act in good faith on behalf of their patients in emergency situations. Successful civil litigation regarding an issue of consent theory against an emergency physician acting reasonably, and consistent with the appropriate standard of care, is extremely rare.[82] An emergency physician is much more likely to be sued for failure to treat while waiting for consent than for providing reasonable treatment without consent.

Federal versus State Laws

Both federal laws (e.g., EMTALA) and state laws govern consent.[5,39] EMTALA comes into play primarily in the evaluation of minors and with patient refusal of an examination, stabilizing treatment, or transfer. State consent laws vary widely and may be set by statutes or case law, or both. The concepts discussed next are generally applicable to emergency medical care, but all emergency physicians should learn the consent laws specific to their own state.

The law presumes that an adult is mentally competent to make medical decisions and that the competent adult is entitled to sufficient information to make an informed decision concerning the physician's proposed course of examination and treatment.[82] Under the doctrine of informed consent, physicians have the duty to disclose the following information to patients[82-84]:

- The patient's condition or diagnosis
- The nature and purpose of the proposed treatment, including the likelihood of success in the physician's practice
- Reasonable alternative measures related to the diagnosis and treatment, including the probable outcome of those alternatives
- The particular known inherent risks that are material to make an informed decision about whether to accept or to reject the proposed treatment, including the consequences of refusing that treatment

Reasonable Person versus Professional Disclosure Standard

The states are split on the standard used to determine what should be disclosed for patients to make informed decisions, but most require the reasonable person standard of disclosure. Under this standard, a physician is required to disclose all of the information that a reasonable person would require to make a decision under the facts and circumstances of the case. The less frequent standard, the professional disclosure standard, requires the physician to provide the same information that other physicians in the community would provide to patients in the same or similar circumstances. This is less stringent than the reasonable person standard.[82,84]

Physicians are not required to disclose every remote risk associated with a procedure or risks that are common knowledge or obvious to the patient, such as the risk of infection after wound repair.[85] The law requires disclosure only of risks that are material, as judged by their seriousness or chance of occurrence. Courts define *material information* as information that "the physician knows or should know would be regarded as significant by a reasonable person in the patient's position when deciding to accept or reject the recommended medical procedure."[86]

Some states legally require physicians to disclose specific risks, such as death.[85] Some states statutorily require a physician to meet both the reasonable person standard and the professional disclosure standard.[87,88]

Physician Role in the Consent Process

The physician who proposes to undertake the procedure must be the one to obtain the patient's informed consent. The duty to obtain consent cannot be delegated, so physicians cannot ask nurses or other health care providers to obtain patients' consent on their behalf. The physician who will care for the patient is best qualified to discuss the treatment and its risks and benefits with the patient. Nurses as well as physicians not skilled in performing the procedure cannot obtain valid informed consent.[89]

The physician should write or dictate into the patient's medical record a summary of the discussion held with the patient and family concerning the elements of informed consent. Particular attention should be made to documentation of those material risks discussed with the patient before the patient's consent is obtained.

Consent is a *process*, not a signature. A written, signed, separate consent form is not legally required under the doctrine of informed consent; however, hospitals may require emergency physicians to complete standardized consent forms and to obtain the patient's signature. The signed form is not a substitute for the consent process. It cannot replace the exchange of information that occurs

www.ketabpezeshki.com 66485457-66963820

between the physician and the patient and family, the answering of questions, and the ultimate agreement of the patient to undergo the medical or surgical intervention.[82]

A signed, written consent form, however, does constitute some evidence of a valid consent. In some states, a signed consent form is presumed to represent valid consent unless that presumption is rebutted by proof that the consent was obtained by fraud, deceit, or misrepresentation of material fact.[90]

Implied Consent in Emergency Situations

If an unconscious or incapacitated patient cannot express consent, the law will assume the patient consented to treatment for the emergency situation. Implied legal consent is premised on two principles: (1) duty to obtain informed consent is excused if death or irreparable harm may result if the physician delays providing treatment, and (2) the law presumes that a reasonable, competent, lucid adult would consent to lifesaving treatment.[91]

The emergency treatment allowed is limited to the circumstances of the emergency, however, and only treatment required to resolve the emergency should be undertaken without consent. Similarly, the emergency condition must require immediate medical attention, with insufficient time to inform the patient or to seek consent from another person.

Courts differ on the definition of a "true emergency," and whether the emergency exception applies in a given case depends on the definition accepted by the court and the application of that definition to the particular set of facts. Fortunately, the courts generally will stretch the doctrine to protect physicians who act in good faith in caring for a patient with a perceived emergency condition.[92] This is one situation in which use of the when-in-doubt rule and documentation of the physician's concerns will weigh greatly in the court's determination of whether the physician acted appropriately without obtaining informed consent. Physicians can further protect themselves by obtaining a second opinion that a true emergency exists.

Minors

Minors Accompanied by a Parent or Legal Guardian

Parents and legal guardians have the right to consent on behalf of their minor children. However, they need to act reasonably and in the best interests of their children. If they do not, their right to consent can be abrogated by the state or the courts. Parents are not allowed to refuse treatment for a child with a life-threatening emergency condition. The management of children with emergency conditions whose parents refuse to give their consent to treatment is discussed later.

Either natural parent of the minor child may provide legally binding consent. If one parent agrees with a proposed treatment and the other does not, consent may be accepted from the agreeing parent. Even if separated or divorced, either parent may give consent unless one parent has been judicially granted sole legal custody of the child, in which case only the custodial parent may consent. The child's biologic father, even if never married to the mother, also may consent for his child.

Unaccompanied Minors

EMTALA mandates that all persons presenting to an ED requesting care be examined to determine whether an emergency condition exists.[5] Because EMTALA is federal law, it takes precedence over all state consent laws regarding the initial evaluation of a minor child. In essence, the child's mere presence at an ED requesting examination or treatment constitutes legal consent to examination of the child to determine whether an EMC is present. Furthermore, the hospital should not delay this initial screening evaluation to wait for consent from a parent or legal guardian (and nurse triage does not qualify as the required medical screening, no matter how nonurgent the child's condition appears to the nurse).

If an EMC is discovered through the initial screening examination,[5,39] the physician may treat the emergency under either state or federal legal theories. First, under state laws, the standard emergency exception doctrine applies. State laws allow physicians to proceed with treatment whenever an emergency exists. Although no uniform legal definition of emergency exists among the states, state laws tend to define an emergency liberally, such as "any threat to the minor's life or health." The courts almost always affirm a physician's judgment about an emergency condition and rarely question the treatment given to a minor without parental consent.[93] Preserving life, preventing permanent disability, alleviating pain and suffering, and avoiding eventual harm have been used as guidelines for emergency treatment without consent.[93] Any minor presenting to the ED should be triaged and provided with an MSE to determine whether an EMC exists.

Under EMTALA, if an EMC is present, the hospital and physicians are required to provide "stabilizing treatment."[39] Federal law also gives the physician broad discretion to decide what treatment should be performed and in what time frame it should be accomplished. The stabilization requirement includes transfer as necessary to an institution capable of handling the minor's emergency condition. Thus, under federal law, a minor could be examined, stabilized, or transferred to another institution without consent ever being obtained from the family; in this instance, the care would be not only in the patient's best interest but also legally mandated.[5,39]

In general, if the MSE does not reveal an emergency condition, physicians need to obtain proper consent from the minor's parents or legal guardian. However, state laws and the courts have applied a number of exceptions to allow minors to seek treatment on their own without parental consent. These exceptions vary widely from state to state, and most are applied through an analysis of facts and circumstances on a case-by-case basis by the courts. Under the *mature minor* exception, minors who possess an understanding and appreciation of the nature and consequences of the treatment and appear competent to make their own decisions are allowed to consent, despite not having reached the defined age for maturity (usually 18 years).[94] A mature minor usually is 15 to 17 years old.

The *emancipated minor* provides another exception to the need for parental consent. If the minor is living independently, is self-supporting, or is in the U.S. Armed Forces, the courts may recognize the minor as emancipated and able to consent on his or her own behalf. Again, this is determined by the courts on a case-by-case basis.[95] In addition, most states have statutory reasons, such as sexually transmitted diseases, pregnancy, or domestic violence injuries, that allow minors to seek care without the consent of their parents.[96]

Incompetent or Incapacitated Adults

If a person has been declared legally incompetent by a court, consent must be obtained from the person's court-appointed legal guardian. In addition, people may appoint legal surrogates to make legal decisions for them should they become incompetent. State-sanctioned living wills, advance directives, and durable medical power of attorney documents all transfer consent powers from a person who becomes incompetent to a legally appointed surrogate.[97]

If an incompetent adult has neither a legal guardian nor an appointed surrogate, physicians typically look to the patient's family for consent to treatment. However, consent to treatment by a family member, even the patient's spouse, generally is not

www.ketabpezeshki.com 66485457-66963820

acceptable under American law unless the spouse or family member has been appointed legal guardian by a court of proper jurisdiction.[98] Marriage does not confer one spouse the legal capacity to consent to medical treatment for the other spouse, even when the ill or injured spouse is incompetent.

Some states recognized this problem and enacted "family consent statutes," which outline a hierarchy of family members who can legally provide consent when the family member becomes incapacitated.[99] However, even when families have no legal standing to consent for the incompetent relative, it is wise to involve family in the medical decision-making process. Communication and concern for the family will avoid misunderstandings, surprise, and anger, which are the primary sources of litigation. Fortunately, if an emergency exists, no authorization from family is necessary to provide such reasonable care as is necessary to correct the life-threatening situation. Once the emergency is resolved, consent should be obtained from someone authorized to act on behalf of the incompetent patient. If there is no appointed legal guardian or surrogate and no state statute on family consent, the physician will need to seek consent authorization from the courts. The courts may appoint a guardian at that time, generally a family member, or after judicial review of the issues, the court itself may grant consent on behalf of the incapacitated person.

Other Special Populations of Patients

Prisoners

Competent prisoners generally do not surrender the right to consent by virtue of being incarcerated. However, a state or court may compel treatment on the basis of interests perceived as paramount to the prisoner's interests.[100] The elements usually necessary to treat self-inflicted injuries over the objection of the competent prisoner include the following[101]:

The injury to the prisoner was willful and intentionally self-inflicted.

The proposed treatment is necessary to preserve or to restore the health of the prisoner.

The prisoner refuses to give consent.

The physician documents the medical indications for treatment in writing in the prisoner's medical record.

Alcohol-Intoxicated Patients

Alcohol intoxication itself may not render a patient incompetent to give informed consent.[102] The emergency physician should evaluate each situation individually to determine whether the patient is incapacitated by alcohol to the extent that he or she is no longer able to understand the proposed treatment, risks and benefits, and rational alternatives. In essence, the general rules for determination of whether a patient is competent to make informed decisions cannot be disregarded just because the person is intoxicated with alcohol. However, the when-in-doubt rule is particularly applicable in these cases because alcohol intoxication often is associated with occult serious illness or injury.

Alcohol intoxication, particularly if it is documented by a measured blood alcohol concentration (BAC), is strongly suggestive to courts and juries of impaired mental status, even though health care workers recognize that many alcoholics are entirely rational and competent at fairly high BACs.[23,103,104] Conversely, low BACs do not guarantee competence because other processes (e.g., hypoglycemia, blood loss, impairment from other illicit substances) may cause the patient to be incompetent. Thus the patient's clinical capacity is more important than the specific level of alcohol in determining competence.

One advantage of obtaining a BAC is that some states allow blood samples drawn solely for medical purposes to be subpoenaed later by the prosecutor for use against the driver in a driving-while-intoxicated prosecution or other criminal charges.[23,105]

The state "legal limit" of intoxication is not a measure of a patient's competence. The legal level for driving has little if anything to do with the capacity to make informed medical decisions. However, this distinction is sometimes difficult for judges and juries to understand, and the emergency physician can actually use the blood level to support a judgment that the patient was not competent to make informed decisions in a particular instance. At other times, it is better not to have a "number," so that the only relevant criterion for determination of the patient's competence is the physician's judgment.[103]

Patients Given Pain Medications

Obtaining informed consent from patients treated with pain medications before a procedure is a common issue. As with alcohol intoxication, the mere fact that a patient has been given narcotic analgesia does not render that patient incapable of consenting to surgical procedures. Plaintiff attorneys can always argue "the patient was too snowed with drugs to give consent"; on the other hand, they can equally argue that the patient was "in too much pain to consent and would have agreed to anything to stop the pain." Accordingly, when consent is sought from a patient who has received pain medication, the patient's ability to understand the ramifications pertaining to the procedure should be assessed and taken into consideration, involving the family in the process if possible. The physician should document that the patient's premedicated state was considered in judging the patient's competence to make an informed decision.

REFUSAL OF MEDICAL CARE

Informed Refusal

The corollary to a patient's right to give informed consent is the patient's right to refuse medical care, even if such refusal results in death. In *Cruzan v Director, Missouri Department of Health*, the U.S. Supreme Court determined that a competent adult has a constitutionally protected right to refuse medical care.[106] However, that right is not absolute. Under particular circumstances, courts will consider countervailing compelling state interests, such as preventing suicide, preserving life, and protecting innocent third parties.

Physicians who honor a competent patient's decision to refuse treatment are not liable for any resulting bad outcome.[107] In fact, physicians are more likely to be successfully sued for treating patients over their objections or without their consent, even when the treatment is lifesaving.

When a competent adult refuses indicated medical intervention, it often is because of fear, anger, misunderstanding, or some other failure in communication in the physician-patient relationship. Before allowing a patient to refuse care, the physician should try to determine and resolve the underlying reasons behind the patient's refusal.

The attending physician must always be involved when a patient refuses medical care or expresses the intent to leave against medical advice.[108,109]

As with consent, refusal of medical care is a process, not a signature. It must be an informed refusal; merely having the patient sign an "informed consent to refuse examination, treatment, or transfer" form or an "against medical advice" form is not sufficient. There are four essential components of the refusal process.

Determining Competence. The physician must determine that the patient is competent to make decisions. Normal findings on the mental status examination without evidence of diminished mental capacity from closed head injury, severe pain, hypoxia,

www.ketabpezeshki.com 66485457-66963820

hypotension, alcohol intoxication, mental retardation, or mind-altering substances constitute good evidence of competency. Noting the patient's rationale for refusing care, even if it is not reasonable, provides additional evidence of competency.[110]

Ensuring an Informed Decision. To be legally binding, a decision to refuse a test or treatment or to sign out against medical advice must be an informed decision. The physician should explain the severity of the patient's condition, the potential complications, and the alternative treatments available. The physician should use terms that the patient can understand and provide the patient an opportunity to ask questions. The patient should understand that the risks of refusing care include the possibility of permanent disability and death. Ideally, a witness should be present when the physician informs the patient and any family members.[111]

Involving Others. The patient's family, friends, and personal physician should be involved whenever possible. These persons should hear the same message as that conveyed to the patient because they may be able to persuade the patient to accept the recommended therapy. If the patient expressly forbids the emergency physician to speak with others, as is the patient's legal right, this should be explained to them and documented in the medical record.

Documenting Appropriately. Appropriate documentation of the refusal process is necessary to protect the physician and hospital from inappropriate litigation. The patient should be asked to sign the refusal form.[2,9,112] (Fig. 2 shows a sample AMA form.)

If the patient refuses to sign the form, that fact should be documented and the form signed by a hospital representative who witnessed the patient's refusal. The medical record should reflect the patient's mental status examination findings and competency to make informed decisions, the risks and benefits of recommended treatments, the available alternatives, and the participating family or friends. Documentation of the patient's rationale for refusing treatment, that the patient was treated to the extent allowed by the patient, and that the patient was invited to return for care at any time offers added protection.[112]

Federal Rules

EMTALA requires hospitals to take and to document specific actions when patients refuse medical screening, treatment and stabilization, or transfer. The government and the federal courts presume that the patient requested emergency care and place the burden of proof on the hospital to demonstrate that the patient voluntarily refused care.[2,9,113]

There are essentially two scenarios in which patients leave the ED after refusing examination or treatment. First, some patients simply pick up and leave, without the knowledge of anyone affiliated with the hospital. If the patient's departure is witnessed, the patient does not respond to requests to return for the examination or to discuss the issues with the hospital staff. These patients are generally referred to as those who "leave without being seen" (LWBS) or "leave before examination." In the second scenario, the hospital personnel are aware that the patient is about to leave and have an opportunity to interact before the patient leaves. Hospitals generally refer to this as "leaving against medical advice." The Office of the Inspector General (OIG) and CMS refer to both of these scenarios as "voluntary withdrawal" of the patient's request for evaluation or treatment.[2,9,114]

Leaving without Being Seen

If a patient walks out before the MSE and later has an adverse medical result, the burden will be on the hospital to prove that the person left voluntarily and was not denied examination or treatment by the hospital. The OIG and CMS admonish hospitals about LWBS patients, stating that "hospitals should be very concerned about patients leaving without being screened. Since every patient that presents seeking emergency services is entitled to a screening examination, a hospital could violate the patient antidumping statute if it routinely keeps patients waiting so long that they leave without being seen, particularly if the hospital does not attempt to determine and document why individual patients are leaving, and reiterate to them that the hospital is prepared to provide a medical screening if they stay."[9,25]

Hospitals need to have a policy and practice for LWBS patients that adequately document pertinent findings and protect the hospital from liability. In most hospitals, the staff calls the patient and checks the waiting area at least three times before declaring that the patient has left the department. These serial checks, with time of day performed, should be documented on the patient's record, and once it is evident that the patient is no longer present, the record should be reviewed on a timely basis by the physician on duty. If the reviewing physician discovers something of concern regarding the patient's chief complaint or triage data, the person can be contacted and encouraged to return to the ED. The registration papers, triage records, nursing documentation at triage, and physician's review and documentation of that review should be kept in the patient's permanent record. These records should be retained for a minimum of 5 years to protect the institution should the interaction ever be the subject of a retrospective EMTALA investigation or litigation on behalf of the LWBS patient.[2,9]

Leaving against Medical Advice

If hospital personnel are aware that a patient intends to leave before completion of the MSE or stabilizing treatment for whatever reason (e.g., tired of waiting, changes mind, concerned about cost of care), the hospital should handle and document the interaction carefully to avoid EMTALA or medicolegal liability[2,9,115-117] (Box 4). In each case, the following steps should be taken:

1. *Inform the patient of the hospital's obligation under the law.* The ED staff should inform patients of their rights under the EMTALA to receive medical screening and any necessary stabilizing treatment from the hospital, regardless of their ability to pay for that service.
2. *Determine the patient's competence.* Only legally competent persons can refuse necessary medical care. For example, alcohol-intoxicated patients who present to the hospital with medical complaints cannot be allowed to leave the hospital without examination and treatment until it is determined that they are legally competent to make such a decision.
3. *Explain the risks and the benefits to the patient*. For patients to make an informed consent to voluntarily withdraw their request for services, they need to understand the benefits and the risks of withdrawal before refusing examination and treatment. These risks and benefits should be specific to the patient's chief complaint.
4. *Secure the patient's written informed consent to refuse care.* The hospital should take all reasonable steps to secure the patient's written and informed consent (i.e., obtain a signature) to refuse medical care. A standard form should be used that contains space for documentation of the patient's competence, the risks and benefits discussed, and whether the patient's family was available to be involved in the discussions. If the patient refuses to sign the form and simply walks out after the interaction with the hospital, the person who discussed the issues with the patient and witnessed the patient's refusal should sign the form and document the interaction.
5. *Offer alternative care within the scope allowed by the patient.* It is outside professional practice standards to respond angrily, to act vindictively, or to punish patients when they decide to leave against advice by refusing to provide alternative

Box 4 Protocol for Management of AMA Cases in the Emergency Department

Always involve the emergency physician.
Involve the family or the patient's personal physician whenever possible.
Explain the risks and benefits specific to the patient's condition; "You could die" alone is too generic.
Explain any alternative treatment options to the patient.
Ascertain the patient's capacity to make informed medical decisions: "When in doubt, don't let 'em out!"
Have the patient and at least one witness sign the AMA form.
If the patient refuses to sign the AMA form, a member of the hospital staff should sign the form stating that the patient refused to sign the form.
Always still provide the best possible treatment within the scope allowed by the patient, including antibiotics and analgesics when warranted.
Provide appropriate discharge instructions and welcome the patient to return to the ED at any time if he or she reconsiders and decides to accept the recommended care.
Document discussions with the patient, the risks explained, and the patient's medical decision-making capacity and understanding of the ramifications of leaving AMA in the medical record (and in real time, not hours after the patient has left the ED).

AMA, against medical advice; *ED,* emergency department.

treatments, medications, analgesics, or discharge instructions. Patients always get to define the scope of medical services that they are willing to accept. Accordingly, an appropriate strategy is to negotiate and cajole them into allowing the best possible care under the circumstances that they define. For example, if a patient with "fight bite" tenosynovitis refuses hospital admission, operative intervention, and intravenous antibiotics and analgesia, the next best option can be offered, such as thorough cleansing in the ED, intramuscular antibiotics, and oral narcotics, with recheck in 24 hours. Failing that, cleaning in the home sink, oral antibiotics, acetaminophen, and follow-up with the patient's primary care physician can be recommended.

Negotiation aims for the best alternative that the patient is willing to accept, even if that means providing less than optimal treatment. Pain medications should never be withheld because the patient will not accept the recommended treatment plan. This "strategy" is cruel, further alienates the patient, and serves no useful purpose.

Moreover, patients should always be invited to return to the ED (or encouraged to see their private physician) if they change their mind and become willing to accept the recommended treatment. A patient's refusal of the more appropriate treatments as well as communication of offers to provide treatment within the circumstances proscribed by the patient should be delineated.

6. *Document the interaction in the patient's hospital record.* The medical record, preferably a dictated and transcribed medical record, should accurately relate the interaction between the hospital and the individual refusing the MSE. The record reflects the hospital's conformity to the law and the patient's leaving of his or her own accord—specifically, the risks of refusing the examination and the reasons for the patient's refusal. Documentation of the reasons for refusal provides evidence that the hospital did not economically coerce or in any way financially deter the patient from remaining for the MSE. The chart should clearly indicate that the patient did not leave the department on the basis of a "suggestion" by the hospital concerning any financial issues.

Parent or Guardian Who Refuses Care or Blood Transfusions for a Minor

In general, state laws support parental control of health issues affecting their children. However, the state will not allow parents to deny children needed emergency medical care under the doctrine of *parens patriae,* the state's paternalistic interest in children.[118] All states empower emergency physicians to intercede under their child abuse and child neglect laws.[111,119] When a child's injuries are potentially life-threatening, the emergency physician can take custody of the child under the child abuse laws and provide indicated treatment, including blood transfusions. In deciding whether to act, the when-in-doubt rule definitely applies, and all jurisdictions statutorily protect physicians from criminal and civil liability for acting in good faith to protect children.[111,119]

The courts have specifically addressed the issue of Jehovah's Witness parents attempting to refuse emergency blood transfusions for their minor children. All jurisdictions hold that a parent's right to freedom of religion does not include the right to deny life-sustaining medical intervention for that person's children.[120] One judge best summarized the feelings of the courts: "Not even a parent has unbridled discretion to exercise his or her religious beliefs when the state's interest in preserving the health of the children within its borders weighs in the balance."[121]

Some states specifically address the issue of overriding parental refusal of indicated medical intervention by statute.[122] In North Carolina, for example, if the parents refuse to consent to treatment and the delay to obtain a court order would seriously worsen the child's physical condition or endanger the child's life, and if a second physician agrees that the procedure is necessary to prevent immediate harm, a physician can render treatment without parental consent. If a second physician cannot be contacted before treatment is initiated, the physician may still perform the indicated therapeutic intervention without parental consent.[123]

Conversely, courts refuse to rule against the parents' wishes when the child's medical condition is not serious or life-threatening. If there is no life threat or potential for serious impairment, the parents' refusal should be respected. Parental refusal of indicated nonemergency medical treatment is usually statutorily defined as "child neglect," which is not legally sufficient to take custody of the child. Child neglect should still be reported to the appropriate authorities; treatment for the child can then be obtained under a court order.[119]

Jehovah's Witnesses

Adult Blood Transfusions

The approximately one million Jehovah's Witnesses in the United States believe that blood transfusion destroys their relationship with God and forfeits their chance for eternal life; accepting transfusion is not a minor infraction of their faith.[124,125] They do not accept whole blood, packed cells, platelets, white cells, plasma, or autotransfusion of stored blood. Most will allow the use of crystalloids, albumin, hemophiliac preparations, immunoglobulins, dialysis, and heart-lung machines.[124-126]

Jehovah's Witnesses and the issue of blood transfusion present difficult medicolegal issues in the ED.[127] State courts may have widely divergent views on the issue, and no clear-cut answers exist. However, the current trend is granting patients greater autonomy to refuse blood, even when the state asserts compelling interests to override a person's refusal.

General principles of consent and the when-in-doubt rule apply, but hospitals and medical staff also should develop policies and procedures in advance to resolve potential conflicts with the Jehovah's Witness patients in the community; coordinate the

www.ketabpezeshki.com 66485457-66963820

management of each case with hospital legal counsel, in contact with a judge who can issue court orders when appropriate, if time allows; have other physician consultants write notes of agreement regarding the need to give blood; and communicate effectively with patients and family, in advance when possible.

Competent Adult

The courts have found that "the competent adult has the right to refuse a transfusion regardless of whether his refusal to do so arises from fear of adverse reaction, religious belief, recalcitrance, or cost."[128] This applies "even though we may consider a patient's beliefs unwise, foolish, or ridiculous."[129] However, even this right is not absolute. If the patient's refusal conflicts with compelling state interests such as the preservation of life, the prevention of suicide, or the protection of innocent third parties, the courts may order transfusions despite the person's objections.[127] Previously, typical scenarios in which the courts overrode a competent person's refusal included cases involving pregnant women, to protect the life of the fetus; mothers of young children, to promote the general welfare of the children; and a sole supporting father or mother, to prevent offspring from becoming wards of the state.[130] Some courts, however, have significantly restricted the hospital's or state's ability to assert compelling interests challenging a competent person's right of self-determination.[131]

Unconscious or Medically Incompetent Adult

In an emergency, if the Jehovah's Witness's beliefs are unknown, physicians may transfuse the patient because consent will be implied under the emergency doctrine. It is irrelevant if the spouse, mother, or other family members adamantly refuse to allow the transfusion for religious reasons. The state's compelling interest in preserving life outweighs the family's expression of the patient's religious preferences.[126]

In the past, when a Jehovah's Witness's beliefs and transfusion preferences were known in advance but the patient was incompetent at the time of the emergency, the courts tended to support transfusion until the patient became competent and could refuse transfusion "contemporaneously."[120,132] The modern trend is to accept objective evidence of the patient's wishes, for example, a signed card carried by the patient that identifies him or her as a member of the Jehovah's Witnesses and sets out the religious objection to blood transfusion. The card may be accepted as adequate evidence of the patient's intent, like a form of advanced directive, which is binding on hospitals and physicians. In at least six states, if the card is dated and signed before two witnesses, it is statutorily valid.[133] Even if the blood refusal card does not conform to a state's advance directive statute, it should be considered strong evidence but not necessarily determinative of the Jehovah's Witness's wishes. Advance directives are merely a means to express an individual's rights and are not the exclusive means to express those rights legally.[126,127] Jehovah's Witnesses increasingly use state statutorily defined advance directive methods to legally express their intentions.[134] Emergency physicians should, however, be certain the card or advance directive actually belongs to the patient.

Of interest, no Jehovah's Witness has successfully sued a health care provider to recover damages in cases in which blood was withheld on the basis of an apparently valid blood refusal card. Also, "criminal, civil, or professional misconduct liability has never been imposed on health care providers for forgoing treatment the patient did not want."[135]

REPORTING REQUIREMENTS

All states require hospital EDs to report certain events or illnesses to local public health authorities.[136] The state's primary intent is to prevent the spread of communicable diseases, to protect its citizens from disease and violence, and to prosecute criminal acts. In each instance, the state statute overrides patients' rights of confidentiality. The statutes typically also provide physicians with immunity from civil liability or criminal prosecution if the reporting is done in good faith.[137]

All EDs should maintain up-to-date lists of diseases and incidents that must be reported to the state. The process and responsibility for appropriate reporting should be clearly articulated in departmental policy.

Communicable Diseases

Typical communicable diseases that must be reported include those of epidemiologic concern, such as sexually transmitted diseases (including gonorrhea, syphilis, chlamydial infection, nongonococcal urethritis, and human immunodeficiency virus infection) and highly communicable illnesses (such as tuberculosis, hepatitis, pertussis, and recently methicillin-resistant *Staphylococcus aureus* [MRSA] infection). Emergency physicians also have a duty to warn patients with communicable diseases against activities that may spread the disease and should instruct them to inform contacts to seek evaluation and treatment. Physicians should adequately document such instructions in the medical record to prevent liability to third parties for failure to warn appropriately.

Violent Acts

Wounds, injuries, and illness resulting from criminal acts of violence must be reported to state agencies.[138] Bullet wounds, powder burns, stab wounds, intentional poisonings, child abuse or neglect, sexual assaults, spousal abuse, domestic violence, and any suspicious injuries generally must be reported.

Deaths

All deaths must be reported to state or local authorities. Death under certain circumstances also must be reported to the county medical examiner. Typically these include deaths from violence, poisoning, accident, suicide, or homicide; any sudden death in someone in apparently good health or when unattended by a physician; any death occurring in a jail, prison, or correctional institution or in police custody; and any death occurring under suspicious, unusual, or unnatural circumstances.[139] Fetal deaths also may have to be reported, usually after 20 weeks' gestation or the typical gestational period of possible viability.[140]

When a death requires a report to the medical examiner, the integrity of the scene and the body should be preserved. ED staff should disturb the body as little as possible, secure the patient's belongings and any potential evidentiary materials, and leave in place medical interventions such as endotracheal tubes, nasogastric tubes, and central or peripheral intravenous lines. The medical examiner will determine whether the state will assert authority over the body, order an autopsy, or release the body to the family.[139]

In addition, any death that occurs while the patient is "restrained or in seclusion for behavior management," when it is reasonable to assume that the death is the result of the restraint or seclusion, must be reported to CMS.[141,142] In the ED setting, this typically would involve use of restraint or seclusion as a last resort to address violent behavior presenting a risk to the patient, hospital staff, or others.

Alcohol-Related Motor Vehicle Crashes

At least six states (Hawaii, Indiana, Illinois, Pennsylvania, Rhode Island, and Utah) have mandatory reporting laws governing

www.ketabpezeshki.com 66485457-66963820

alcohol-related motor vehicle crashes.[143] Many other states have laws permitting but not requiring EDs to report intoxicated drivers to authorities on the basis of a known BAC.[143,144]

Animal Bites

Most states require the reporting of animal bites, particularly dog and cat bites, to the local public health department. The states also generally require the reporting of bites by any animals known to be potential carriers of rabies, such as bats, raccoons, skunks, foxes, and cattle, to prevent cases of human rabies and to control the spread of rabies within the animal community.[145]

Substance Abuse

A few states require reporting of substance abuse to local authorities.[146]

VI. SUMMARY

KEY CONCEPTS

A variety of stressors contribute to the potentially unhealthful aspects of EM practice, both during residency training and in practice, including the following:

- Difficult patient and professional relationships
- Diversity of practice elements
- Diminished resources
- Difficult decisions full of uncertainty
- Strategies for maintaining wellness for emergency physicians include:
- Mitigating the impact of shift work with circadian scheduling and sleep strategies
- Strategies for managing difficult clinical encounters such as formal debriefs
- Professional support groups
- Cultivating close family and social relationships
- Developing and maintaining physical fitness and other methods of relaxation and renewal

Wellness, Stress, and the Impaired Physician

Andrew R. Barnosky, Timothy A. Peterson, and Michael L. Epter

PERSPECTIVE

The maintenance of wellness is critical in achieving a satisfying and productive career as a competent emergency physician. Previous definitions of w*ellness* focused on the optimal state of health and well-being achieved through the active prevention of illness.[1] More current concepts of *wellness* consider the multifaceted aspects of a physician's physical and mental health as well as emotional health and well-being.[2] Emergency medicine (EM) as a specialty was still in its formative years when concerns first surfaced about the stressful and potentially unhealthful aspects of practice in this specialty and the impact such stressors could have on wellness and career longevity.[3,4] Although experience has shown that large numbers of emergency physicians enjoy long and fulfilling careers, questions remain about how best to cope with the demands and stresses associated with the practice of EM.

This chapter presents an overview of wellness issues facing the emergency physician, divided into three main sections: major stressors, physician burnout and impairment, and strategies for promoting wellness in emergency practice. A fourth section pertaining to residency training and wellness is also included.

CAUSATIVE FACTORS: MAJOR STRESSORS IN EMERGENCY MEDICINE

A variety of stressors contribute to the potentially unhealthful aspects of EM practice, both during residency training and in practice.[5,6] These stressors generally relate to four aspects of emergency practice: difficult patient and professional relationships, diversity of practice elements, diminished resources, and difficult decisions full of uncertainty.

Difficult Patient and Professional Relationships

Although the ability to provide care for a variety of acute and complicated patients under significant time constraints is a source of gratification for practicing emergency physicians, the challenges imposed on the physician-patient relationship are unlike those in other specialties in medicine. In clinical practice, most physicians have the opportunity to establish a sound relationship with their patients over time; in the emergency department (ED), however, patient and physician are thrust together in a relationship that typically is of high intensity, of short duration, and based on the circumstances of need. Many patients presenting to the ED are often under high levels of emotional stress, in pain, and suffering from anxiety and apprehension. They may have language barriers, organic brain syndromes, psychiatric illness, personality disorders, or altered behavioral states that make them more difficult to evaluate.[7] They may be frequent users of the ED services well known to the staff, presenting with conditions requiring an inordinate amount of time and resources. Communication and conflict resolution challenges between physician and patient may be considerable. Some patients present a danger to the physician, manifesting any of a variety of emotional and psychiatric disorders, including chemical dependency disorders, sociopathic behaviors, personality disorders, and psychosis.[8]

Issues of personal safety remain a major concern among emergency personnel because practice in this setting is more likely to be associated with exposure to acts of violence, verbal or physical threats, a variety of potentially life-threatening infectious diseases, and acts of bioterrorism.[9,10] Dealing with "difficult patients" can arouse a variety of emotions that have a negative impact on the physician-patient relationship, including fear, anger, helplessness, inadequacy, intimidation, vindictiveness, and even hatred. Although such feelings are understandable, they may become a considerable source of stress.[7,11]

Professional relationships may likewise be stressful. Emergency physicians practice "fishbowl medicine." Their practice habits and decision-making are often in full view of all members of the medical staff. Disputes can arise regarding patient management and disposition decisions, spheres of practice, referral practices, specialist on-call responsiveness, and care of the uninsured. Moreover, although it is a less prevalent attitude now than in the early days of the specialty, in some professional circles emergency physicians are not accorded peer respect among colleagues in other specialty areas. Professional status is occasionally an issue in dealings between emergency physicians and hospital administrators, in which the ED may be viewed as a less desirable location for resource allocation compared with other clinical services.[6]

Relationships with other members of the ED staff also may be subject to strain. Because EM practice is often contractually based for physicians, the physician group may not have the same degree of workplace "ownership" and supervisory authority as that enjoyed by physicians in a private practice. Nurses and ancillary personnel generally are not hired by the emergency physician group, and disputes may arise about issues of responsibility and control.[6,12]

Diversity of Practice Elements

The "24/7" nature of emergency practice, coupled with the responsibility to treat all persons at all times, fosters a tremendously diverse practice environment. Work schedules typically include a broad mixture of irregularly assigned days, nights, weekends, and holidays. The practice environment often is chaotic. ED patient visits continue to climb in the United States amid a diminishing

www.ketabpezeshki.com 66485457-66963820

number of hospitals.[13] ED overcrowding and diminished availability of inpatient beds can result in the boarding of admitted ED patients and long waits for new patients to be assessed and treated. ED overcrowding and capacity issues have worsened to the point of crisis in some communities.[14-21] ED staff are subjected to a barrage of intrusive noises, including alarms, monitors, pagers, and telephones, as patients of all ages, presentations, and acuity arrive for evaluation at unpredictable intervals. This diversity is often cited by medical students and residents embarking on a career in EM as a challenging, attractive, and often beguiling feature of the specialty. The older practitioner, after years of struggling to maintain some degree of order within the department, amid a pattern in recent years of increasing volumes and acuity of patients, may tend to view diversity as a major stressor.[5,6,12]

Diminished Resources

In an attempt to maintain financial viability amid an ever-challenging environment driven by diminished reimbursement, managed care, uninsured patients, and increasing costs, most hospitals have had to implement cost-cutting measures. These measures have resulted in a number of important resource limitations with which the ED must contend. These include diminished staffing of nurses, ancillary personnel, and social services; burdensome cost-containment policies and documentation requirements regarding access to diagnostic and treatment modalities and outpatient referrals, specialty consultations, and hospital admissions; inadequate policies providing for the care and disposition of medically indigent patients; and diminished reimbursement for services rendered.[5,6,12,22] Nursing shortages have reduced the ability of some EDs to recruit, to retain, and to build a solid team of seasoned nursing professionals experienced in EM.

In the last 5 years, specialist coverage for general surgery, orthopedics, hand surgery, and plastic surgery has become a national issue facing many EDs. A 2010 survey of ED directors reported that 74% of EDs experience problems with specialist coverage.[23] The unavailability of surgical specialists leads to increased patient wait times,[24] higher risk of adverse events related to longer waits,[25] and greater frequency of transfer to another hospital for care. All of these contribute to increased emergency physician frustration while attempting to provide quality patient care.

Difficult Decisions

Emergency physicians often need to make difficult decisions on the basis of ambiguous or incomplete information. One of the single greatest predictors of stress and job dissatisfaction for emergency physicians is the degree to which they are uncomfortable with uncertainty.[26] The driver of this correlation is likely to be the commitment physicians feel to their patients and the appropriate concerns for patient safety; an intense desire to maximize medical outcomes, the anxiety about the potential for medical mistakes, the pressure of decisions made under time constraints, and the fear of litigation are additional stressors of major importance.[5,6,12]

CONSEQUENCES: THE BURNED-OUT OR IMPAIRED PHYSICIAN

Burnout

The term *burnout* was introduced by Freudenberger in 1975 to refer to feelings of job dissatisfaction caused by work-related stress.[27] It includes long-term physical and emotional exhaustion, resulting in diminished interest in the major activities of the job. Further work has been done by Maslach, who developed a Burnout Inventory to measure and to quantify the severity of burnout within an individual. Burnout can be categorized along three general dimensions: emotional exhaustion (feeling emotionally drained by contact with other people), depersonalization (negative feelings toward patients receiving care), and reduced personal accomplishment (the tendency to reflect negatively on your own work).[28,29] A study performed by the Americal College of Emergency Physicians (ACEP) demonstrated emotional exhaustion to be the single greatest predictor of burnout, with a strikingly high prevalence in the survey population.[26]

Burnout is of special relevance to physicians because it undermines the integrity of the physician-patient relationship, which is the foundation of medical practice and essential to effective service. People in advanced phases of burnout are likely to experience decreased productivity, less satisfaction with work, higher job turnover, lower self-esteem, more physical symptoms, more troubled family relationships, and a variety of affective changes, such as hostility, anxiety, depersonalization, cynicism, and depression. Symptoms of burnout are thought to be potential precursors of more severe manifestations of impairment, including alcoholism, drug abuse, and suicide.[30]

Several studies have documented moderate to high levels of burnout among certain populations of emergency physicians, and few emergency physicians would dispute the particular significance of burnout as an occupational hazard. However, burnout is not an inevitable consequence for all practicing emergency physicians, and effective strategies are available to avoid it. A review of the American Board of Emergency Medicine's longitudinal emergency physician career satisfaction survey demonstrated a relatively high, and constant across time, level of satisfaction with no change in the level of physician burnout during the last 10 years.[31]

Additional information about burnout in EM can be found on the ACEP website (www.acep.org) or obtained by contacting the ACEP Practice Management Department (800-798-1822).

Physician Impairment

Physician impairment exists when a physician's professional performance is adversely affected because of mental or physical illness, aging, alcoholism, or chemical dependence.[32,33] The Federation of State Medical Boards defines an impaired physician as one who is unable to practice medicine with reasonable skill and safety because of a mental illness; a physical illness or condition that adversely affects cognitive, motor, or perceptive skills; or substance abuse. It is estimated that 17,000 practicing physicians are afflicted with substance abuse problems in the United States and that 100 deaths annually among physicians are directly attributable to chemical dependency.[34]

Impairment in a physician colleague often is difficult to detect. The recognition of a pattern of events, rather than a single precipitating incident, may be key to making the diagnosis. Difficulties that arise in the workplace often are preceded by a history of family difficulties, including frequent arguments, periods of separation, extramarital affairs, and divorce. Frequent job changes ("geographic cure") and unexplained time intervals between periods of professional employment also may be signs of impairment. A high value usually is placed on maintaining the source of income, and erosion of hospital duties is one of the last things that may be affected. Patient care responsibilities become neglected, and the impaired physician may exhibit poor medical judgment. The problem may develop during a long period because strong elements of denial are usual among family members and associates as well as in the impaired physician.[34]

Following the ethical principles of beneficence and nonmaleficence, it is important to deal fairly and honestly with colleagues yet to take appropriate actions to protect patients from health care providers who are impaired, are incompetent, or engage in fraud or deception.[33,35] Programs to detect and to treat physician impairment have now been established in every state. A few states have recovery programs that are legislatively mandated, being administered by state medical boards, state medical societies, or

www.ketabpezeshki.com 66485457-66963820

Box 1 Lifestyle Balance: Wellness Strategies for the Emergency Physician

Promote wellness in the professional environment.
- General measures
- Strategies for shift work
- Strategies for managing difficult and violent patients
- Professional support groups

Cultivate close family and social relationships.
Develop and maintain physical fitness.
Cultivate methods of relaxation and renewal.

Box 2 Shift Work Strategies

Work the same shifts as much as possible and keep the same sleep patterns. Compensation should be increased for those willing to work night shifts for extended periods.
Work isolated night shifts, with minimal circadian disruptions.
Consider the *Thomas schedule* for groups: One physician works extended night schedule for 1 month or longer, with isolated nights off being covered by the other group members.
Schedule shift rotations in a clockwise direction, with 1-month minimum time per rotation.
Eight-hour shifts are preferable to 12-hour shifts.
Sleep in a darkened room; minimize disruptions.
For those unable to maintain consistent sleep patterns, use compromise strategies, such as anchor sleep, split sleep periods, or napping, to mitigate circadian disruptions.
Start the awake period with a high-protein meal, switching to complex carbohydrates toward bedtime. Avoid caffeine and high-calorie, high-fat snack food before sleep. Eat meals regularly.
Use bright light (>10,000 lux) for 2 hours after arising as an adjunct in adjusting to new shifts.
Exercise regularly.
Plan regular "quality time" with family and friends.
Do not try to live a day-shift lifestyle while working night shifts.

independent organizations. A carefully structured program is critical to the recovery process, and the goal is to rehabilitate the physician so that he or she may return to the care of patients. The prognosis for recovery appears to be excellent when long-term monitoring is in place. The ultimate goal is rehabilitation of the affected physician, with an eventual successful return to work.[34,36]

COPING STRATEGIES: WELLNESS STRATEGIES FOR THE EMERGENCY PHYSICIAN

The very qualities that characterize medically successful physicians—perfectionism, the drive to succeed, willingness to work long and irregular hours, and ideals of individual service and sacrifice—also may predispose them to neglect their own physical and emotional needs. The formulation of any comprehensive wellness strategy is based on the concept of lifestyle balance and involves the integration of professional goals and responsibilities with needs for self-care and development.[37-39] Cultivation of lifestyle balance involves four basic elements, summarized in Box 1 and discussed here.

Promoting Wellness in the Workplace

A strong predictor of job satisfaction among professionals with demanding and stressful jobs is the degree to which they have control over the work flow and job responsibilities in their workplace. Emergency physicians can introduce more control over elements of their practice by ensuring adequate physician and support staffing to accommodate patient load; ensuring adequate input in the development of departmental policies and procedures; cultivating relationships among physicians and staff; and mitigating noise, light, space, crowding, wait times, and structural discomforts.[40,41]

The irregularity of scheduled hours is a major workplace issue for emergency physicians. Shift changes often are cited as a major cause of dissatisfaction within the specialty.[12,40] Shift work is associated with a variety of adverse effects on physical and emotional health.[42-44] These include an increased incidence of peptic ulcer disease, depression, mood swings, drug and alcohol abuse, altered immune response, chronic hypertension, cardiovascular mortality, infertility in women, divorce, work-related accidents and errors, and compromised learning ability when fatigued.[45] In addition, shift workers are more likely to sustain work-related accidents (e.g., percutaneous injury).[46] Approximately 25% of persons in the North American population are shift workers, and research has shown that an estimated 20% of people cannot tolerate shift work.[45,47,48] Rest breaks during shift work may mitigate stress and fatigue, yet this is difficult to achieve.[49] A variety of shift work strategies have been proposed as a means of mitigating these effects (Box 2).[50]

Professional support groups also can help emergency physicians with issues of coping and control over the stressful aspects of their practice. In the process of sharing relevant information, relating personal experiences, listening to others' experiences, and providing sympathetic understanding, members of support groups can cope in a more effective manner. The ACEP has a Wellness Section devoted to consideration of such issues and has sponsored policies and programs to address them. The ACEP also has a speaker's bureau consisting of members who are available to address a variety of wellness-related issues.

A particularly important form of support group relates to *critical incident stress debriefing*. Critical incidents are witnessed traumatic events that have sufficient emotional power to overcome the usual coping abilities of people exposed to them. EM is a field in which situations occur that may cause physicians and other ED personnel, regardless of rank, years of service, or gender, to experience unusually strong emotional reactions that have the potential to interfere with their ability to function. Emergency physicians are continually being exposed to critical incidents, including serious multiple-casualty incidents, pediatric injuries or deaths, line-of-duty deaths, injuries to ED personnel, events of excessive media interest, and events involving victims known to ED personnel. The impact of a critical incident often goes unrecognized even after common stress reactions appear. Although physical and emotional stress reactions are often considered normal and usually will diminish in time, intense or prolonged reactions may have adverse effects on physician and staff well-being.

Personnel exposed to such critical incidents can be subject to the cognitive, emotional, and physical sequelae of the posttraumatic stress syndrome. Components of this syndrome include a continual reexperiencing of the event in thoughts, dreams, or daily life; an avoidance of any stimuli associated with the event; a sense of numbness to one's emotions; and a wide variety of other symptoms, including sleep disturbance, irritability, anxiety, and loss of emotional control.[51]

The concept of critical incident stress debriefing has evolved during the past 30 years from the combined experiences of a variety of emergency services and military personnel. Debriefings are structured group meetings that emphasize venting of emotion and discussion of other reactions to a critical event.[52] The two main goals are lessening of the short-term emotional impact of distressing events and the acceleration of recovery from such events before stress reactions occur. Formal critical incident stress debriefing teams are available in many communities through local emergency medical services agencies. Debriefings also can occur on an informal basis in the ED. Such sessions can take the form of impromptu meetings of emergency and rescue personnel involved in specific incidents in which the details of a particular

www.ketabpezeshki.com 66485457-66963820

event and its associated emotional content are expressed and shared among members of the team.[50] It is important for those involved in leadership roles to make some form of critical incident debriefing processes available when such events occur.

Family and Social Relationships

Many physicians are overly dedicated to their work and prone to delay sources of emotional gratification outside the work environment. These qualities, which may promote a high degree of professional success and satisfaction, also may interfere with the development of family and social relationships, a problem that may be compounded for emergency physicians by their irregular hours.[53-55] The ability to develop and to sustain intimate relationships may be the most critical element in any wellness formula. The simplest and most profound way to maintain mental health while actively absorbed in a demanding career is to establish and to cultivate a viable and genuine relationship with a caring, emotionally expressive spouse or significant other. The promotion of a close family relationship involves, at the very least, a willingness to assign and to prioritize protected time with spouse and other family members. For many physicians, it also involves a conscious effort to develop communication skills, particularly with respect to active listening and the open expression of feelings.[55]

Physical Fitness

Physical fitness is an important concern for emergency physicians, given the rigors of a typical EM practice. For physicians generally, frequency of physical training has a positive correlation to overall life satisfaction.[56] Unfortunately, the obstacles to development of a comprehensive fitness program may be considerable. Factors such as the irregular hours, the hectic work pace, and the variable quality of hospital menus complicate the task of establishing and maintaining exercise regimens and healthy dietary habits. The impact of proper diet and exercise on a variety of wellness parameters is clearly established. Documented benefits of an appropriate diet include lower cholesterol levels, weight control, augmented blood pressure control, and lower incidence of certain cancers. The American Heart Association (AHA) periodically provides dietary guidelines, as summarized in Box 3.[57]

The benefits of a regular and vigorous aerobic exercise program include enhanced exercise tolerance, cardiovascular fitness, lower blood pressure, increased high-density lipoproteins, decreased triglyceride levels, augmented weight reduction efforts, lessened anxiety and depression, improved glucose tolerance, enhanced endurance, and improved flexibility and strength. According to current AHA guidelines, cardiovascular fitness is best maintained by a program of aerobic exercise (the repetitive use of large muscle groups) three to six times per week for at least 30 minutes per session. Strength-developing activities (resistance training) should be performed at least twice per week, with 8 to 10 exercises that use the major muscle groups of the legs, trunk, arms, and shoulders. A regimen of one or two sets of 8 to 12 repetitions of each exercise is recommended. The exercises should be vigorous, sufficient to raise heart rate to at least 50% of maximum (the recommended average maximum heart rate is 220 minus age).[58] Physicians' physical activity levels also influence their attitudes toward physical activity as regards patient counseling practices.[59]

Relaxation and Renewal

In dealing with the innumerable stresses of emergency practice, physicians must be equipped with considerable emotional resources, derived in part from strong peer and personal support systems. Methods of relaxation and renewal are important additional elements.[6,38,40]

Box 3 American Heart Association Dietary Guidelines

Restrict total fat to ≤30% of total calories.
Restrict saturated fat to <10% of total calories.
Limit the total intake of cholesterol-raising fatty acids (saturated and *trans* fats) to ≤10% of calories.
Limit cholesterol intake to <300 mg/day.
Replace cholesterol-raising fatty acids with whole grains and unsaturated fatty acids from fish, vegetables, legumes, and nuts.
Limit sodium intake to ≤2400 mg/day (≤6.0 g/day of salt).
If alcohol is consumed, limit intake to two drinks/day for men, one drink/day for women.
Eat at least two servings of fish per week.
Eat five or more servings of vegetables and fruit per day.
Eat six or more servings of grain products per day.
Emphasize daily intake of low-fat or nonfat dairy products.

Emergency physicians must continually cultivate the ability to remain functional and emotionally resilient when facing the turbulence of the typical ED. Physiologic correlates of stress—increased heart and respiratory rates and increased blood pressure, oxygen consumption, and serum lactate level—can be normalized by a variety of relaxation techniques. These include prayer, Zen, yoga, transcendental meditation, autogenic training, cultivating mindfulness, and progressive relaxation. Studies indicate that the regular use of such techniques can allow development of considerable control over the relaxation process.[60-62] In some physicians, a reduction in clinical workload may be necessary to achieve a satisfactory lifestyle balance.[63]

A final element in the promotion of wellness and lifestyle balance is the concept of *renewal*. Physicians typically develop a work ethic that makes it difficult to disengage from medical responsibilities. A single-minded devotion to career ultimately is impoverishing, and by neglecting restorative activities, physicians tend to lose their emotional resilience.[38,64] The concept of renewal involves the ability to prioritize and to establish time for rest and revitalization as well as spiritual, emotional, and intellectual growth. Stress reduction, maintaining strong personal health and lifestyle balance, a strong social network, and self-reflection are key.[65,66] Out of the maelstrom that constitutes a typical day in the ED, emergency physicians should look to sources of renewal as key elements in their formula for lifestyle balance.

RESIDENCY TRAINING AND WELLNESS

Residency training across all specialties is known as a time of intense study, personal sacrifice, and fatigue. Despite that literature on resident burnout is in the preliminary stages, studies suggest that residents experience high rates of burnout that may be detrimental to both physical and mental well-being as well as to work performance.[67] Whereas many of the stressors that affect emergency physicians in practice are germane to EM residents (e.g., difficult patient and professional relationships, diversity of practice elements, and diminished resources), there are several specific stressors that are magnified during training, most notably, time demands and work hours, autonomy, and maintaining a balance between achieving personal and professional goals.[67-72]

Time Demands and Work Hours

Multiple studies of factors that contribute to resident burnout focus on the issue of time management. In contrast to the attending physician, residents work longer hours and have additional responsibilities beyond the clinical environment. This places an additional constraint on their time, leaving fewer opportunities

www.ketabpezeshki.com 66485457-66963820

to pursue outside interests, and can result in work-home interference.[67,68,71] The role of work-home is dichotomous; interference can lead to emotional exhaustion and depersonalization, whereas having a supportive home situation is protective against depersonalization.[67,71]

In response to both patient safety and resident well-being, the Accreditation Council for Graduate Medical Education (ACGME) implemented common duty hour standards in 2003. Most notably, the limitation of duty hours to 80 hours per week was established.[73] Despite implementation, the prevalence of burnout has remained high, suggesting that duty hour limitations in isolation are not an effective measure for combating the effects of burnout.[67,72] In 2011 the common standards underwent additional revision to reflect the multifactorial aspects of patient care. Included within these updated standards are further reductions in the work hours pertaining to the maximum duty length (e.g., 16-hour cap for postgraduate year 1, 24-hour cap for postgraduate year 2). These changes reflect data from studies of the negative consequences for physicians with shift lengths longer than 24 hours—increased risk of burnout, needle-stick injuries, motor vehicle crashes or near-miss accidents, and medical errors.[71] Further investigation is needed to determine whether these common standards are achieving their end goal and to evaluate their implications for the future of graduate medical education.

The ACGME Residency Review Committee for Emergency Medicine has been even more proactive in an attempt to facilitate a balance between safety, well-being, and training through EM-specific duty hour requirements, including the limitation of shift length, overall duty hours, and protected time free of educational and clinical responsibility.[74]

Lack of Autonomy

An imbalance exists between the vast clinical, research, didactic, and administrative responsibilities for which residents are held accountable and the level of autonomy provided to them during training. Restrictions on their decision-making, autonomy, and scheduling can form the basis of increased job dissatisfaction and stress. This is a classic example of the *demand-control-support model,* in which occupational stress leads to burnout when there is an imbalance between high job demands and low provider autonomy.[67,71]

Fear for Personal Safety and Well-Being

Approximately 50% of EM residents express trepidation about their personal safety, and as many as 22% fear being shot or assaulted.[75] As a result of working more total clinical hours in contrast to attending physicians, residents are at greater risk for work-related incidents, including needle-stick injuries. Despite the low seroconversion risk of human immunodeficiency virus (HIV), 72% of EM residents worry about the potential for needle-stick injury from an HIV-positive patient, and more than half have sustained a needle-stick during training.[75] Outside of the risks of patient care and the potentially unsafe work environment of the ED, EM residents sustain a higher number of near-collisions and motor vehicle crashes after night shifts.[76]

Consequences of Stress

As a result of the inherent stressors associated with emergency practice, physicians who do not establish effective coping mechanisms may go on to experience depression, suicide, troubled interpersonal relationships, loss of identity, and substance abuse.[68,70,71,77] In an effort to increase awareness of those impaired and at-risk residents, the prevalence of substance use among EM residents was restudied in 2006.[78] This anonymous, self-reported survey comprised nearly 2400 EM residents. Marijuana, cocaine, nonprescribed benzodiazepines, and other sedative drug use has decreased in residents reporting any previous use of these drugs compared with the original data published by McNamara and colleagues.[79] However, tobacco use (1992: 41.1% vs. 2006: 45.7%) and use within the past year of cocaine, benzodiazepines, other sedatives, and noninjectable opioids were not statistically different, and past-month and past-year use rates for alcohol and marijuana have increased between the two studies. In fact, there has been a 48% relative increase in daily alcohol use from 3.3 to 4.9%, with 12.6% of residents reporting that their alcohol consumption has increased during residency (1992: 4%) and 5.3% of residents reporting initiation of alcohol use during residency compared with only 0.3% in 1992.[78,79] Examined against data provided by the National Survey on Drug Use and Health and the Behavioral Risk Factor Surveillance System for similar age groups, resident past-month use of alcohol is strikingly higher, even though no significant difference in response to CAGE screening questions was identified compared with 1992.[78,79]

The consistent and concerning finding between the two studies is that of detection. In 1992, 13% of EM residents had a CAGE score consistent with alcoholism, but program directors believed that only 1% of their residents had a suspected alcohol problem.[79] In 2006, 5.2% of EM residents reported feelings of impairment, compared with 2.9% in 1992, but only 1% were diagnosed and treated for substance abuse.[79] Those respondents who were most likely to have positive CAGE scores during residency were single, separated, or divorced.

With the pressure of longer shifts and total clinical hours, it is not surprising to find that use of caffeine is universal: 90% of EM residents report using caffeine in the past month, and 66% consume caffeine on a daily basis.[79] Despite the finding that 60.8% of EM residents indicate that they use some kind of chemical to help stay awake, modafinil and zolpidem—drugs marketed to reduce symptoms of sleeping disorders, including shift work sleep disorder—are used by only 2.4% and 21.8% of EM residents, respectively.[80] For those residents who strategically use zolpidem, it is most often in association with transition to and from night shifts.[80] Use of either modafinil or zolpidem does not appear to be associated with the use of other substances, including those most commonly used (caffeine, alcohol, and tobacco) and illicit drugs (cocaine, amphetamine, and marijuana).[78,80]

Finding Balance and Well-Being

Because most literature dealing with resident wellness focuses on the negative aspects of well-being through use of quantitative scales (e.g., Maslach Burnout Inventory), Ratanawongsa and colleagues focused their research on the identification of factors associated with positive well-being. The six themes that emerged from this qualitative study were the following: (1) balance among multiple domains, (2) professional development and temporary imbalance, (3) professional satisfaction and accomplishment, (4) maintaining a sense of self, (5) stressors and coping strategies, and (6) the role of residency programs.[70] These inter-relationships form the basis of the proposed conceptual model of well-being. In this model, coping strategies, professional satisfaction, accomplishment, and maintaining a sense of self promote higher levels of well-being.

On the basis of the results of this study, shared responsibility between the individual resident (ensuring balance and maintaining a sense of self) and the residency program (professional development) are essential to optimization of wellness. Ensuring balance and maintaining a sense of self are integral components to any wellness prescription and are more likely to result in a positive training experience. Potential domains for residents to

www.ketabpezeshki.com 66485457-66963820

prioritize include professional, personal, spiritual, and intellectual growth; family and social interactions; health; and finances.[68,70,81] As with any prescription, prioritization is highly individualized.

Culture Change

The traditional approach in resident education of rewarding individual achievement, independent judgment, and self-sacrifice teaches the notion that physicians are indestructible, have few needs, do not make mistakes, and are never ill.[68] Cedfeldt discusses the idea of a "hidden curriculum" within residency programs whereby residents are reluctant to negatively affect a colleague's schedule for fear of appearing weak.[69] A culture change away from perceived stigmas like these is necessary; a primary focus must be placed on wellness and the appreciation that wellness is simply not the absence of burnout.[67,71,81,82] On a macro level, establishment of a formal wellness curriculum within residency programs with a foundation built on endurance and vitality and resident assessment and goal formation creates an environment to produce meaningful change while maximizing professional satisfaction.[82] Research suggests that resident well-being may begin to be improved through restoring meaning to residents' time commitments, facilitating supportive and transparent communication, increasing resident work control, and protecting the separation of work-home.[67,69,81] Examples of strategies to accomplish this and to realize the benefits of culture change include prioritizing short- and long-term goals through evaluation and needs assessment; support groups[68,72,81]; forums for providing feedback[70]; schedule flexibility (considered to be more valuable than limiting of duty hours)[70]; discussing wellness-centered topics[81]; establishing policies to protect resident time off[69]; enhancing opportunities for growth, learning, and responsibility; and endorsing personal and program accomplishments.

As graduate medical education continues to evolve, both programs and residents are faced with new challenges that have a multidimensional impact on resident education and wellness. Continuing to maintain a proactive approach to these challenges, both institutionally and personally, is essential to change the culture toward one of endurance, longevity, and vitality.

SUMMARY

Many aspects of the practice of EM are potentially threats to wellness. Emergency physicians can hope for less stressful, more fulfilling careers by adopting strategies to enhance personal and professional well-being.

KEY CONCEPTS

A variety of stressors contribute to the potentially unhealthful aspects of EM practice, both during residency training and in practice, including the following:

- Difficult patient and professional relationships
- Diversity of practice elements
- Diminished resources
- Difficult decisions full of uncertainty
- Strategies for maintaining wellness for emergency physicians include:
- Mitigating the impact of shift work with circadian scheduling and sleep strategies
- Strategies for managing difficult clinical encounters such as formal debriefs
- Professional support groups
- Cultivating close family and social relationships
- Developing and maintaining physical fitness and other methods of relaxation and renewal
